

**Laser sintering of hydroxyapatite
by layer-wise slurry deposition (LSD)**

Dissertation

zur Erlangung des Grades eines
Doktor-Ingenieures

vorgelegt von

Dipl.- Ing. Zahra Sadeghian

aus Teheran (Iran)

genehmigt von der

Fakultät für Bergbau, Hüttenwesen und Maschinenwesen
der Technischen Universität Clausthal

Tag der mündlichen Prüfung

15. März 2005

Hauptberichterstatter.....Prof. Dr. Ing. J. G. Heinrich
Berichterstatter.....Prof. Dr. Ing. J. Deubener
Vorsitzender der Prüfungskommission.....Prof. Dr. Ing. H. J. Barth

To my Family and my Teachers

"You have to believe yourself. If you want, you can. Only decide"

Acknowledgements

First of all, special thanks to my God who has always helped me. I would like to express my deepest gratitude to Prof. Dr. Ing. J. G. Heinrich and Prof. Dr. Ing. F. Moztarzadeh for their strong support and their friendly assistance. They have taught me the way how to focus on the research and being serious in working to achieve good results. They offered me an ideal scientific atmosphere and helped me to gain a knowledge and ability beyond the reach of many attainments.

I would also like to thank Prof. Dr. Ing. J. Deubener for becoming my second examiner and for spending his precious time in reviewing my thesis.

I would like to thank to all my colleagues in this institute, who had helped me in various technical and personal matters, during my entire in this institute in particular Dr. Günster, Mr. Engler and Mr. Gahler and Dr. Ohlendorf for their support in set up of the LSD device. I would like to thank Mr. Gorke, Mr. Betram, Mr. Zellmann, Dr. Dörr, Dr. Hensch, Mr. Shütz, Mr. Holly and Mr. Rust in particular Mrs. Luer and Mrs. Ohlendorf for their kind helps.

Finally, I would extend my thanks to all my family members who have been a continuous source of encouragement and support. My special thanks to my mother, my husband and my lovely daughter for their patience and continuous encouragement.

Abstract

Layer-wise slurry deposition (LSD) is an approach in solid freeform fabrication (SFF), that can be used for fabrication of hydroxyapatite (HA) bone implants. In view of biocompatibility, HA is a suitable ceramic material for hard tissue replacement implants. SFF technique is the prototyping of objects directly from computer models without part-specific tooling or human intervention.

A slurry is processed by a LSD device designed by the Clausthal University of Technology. The general purpose of this method of rapid prototyping (RP) is to reduce the time for product development by shortening the period between design and testing without using of any mould. Another useful feature of the technology is to provide a relatively simple interface to the sliced geometry from computer aided design (CAD) solids models of sources such as computed tomography (CT) and magnetic resonance imaging (MRI) images.

LSD process is sequentially layering of slurry and then laser sintering of these layers. The aim of the present work is to analyze the influence of laser parameters on the LSD fabrication process of HA implant. The rheological properties of the hydroxyapatite slurries play an important role in facilitating the layering operation. The most influential process parameters on microstructure and composition of the samples are laser power and laser beam speed. The current work focuses on the preparation of stable-dispersed HA ceramic slurries for LSD and investigation on the effects of laser parameters on the LSD process and penetration depth. X-ray diffraction (XRD), fourier transformation infrared spectroscopy (FTIR) and scanning electron microscopy (SEM) were used to investigate the influence of laser parameters on the formation of the phases. After laser sintering the presence of α -tricalcium phosphate (TCP) and amorphous calcium phosphate (ACP) was detected. TCP and ACP are beneficial for accelerated fixation and remodeling of the prosthesis. The laser sintered samples have a high porosity that the pore size of samples expressed as a function of laser parameters and green density of layer.

Also, this current work includes comparing of the direct laser sintering process with conventional sintering of layers.

Also, in this study, the fabrication of the porous and dense glass-reinforced HA composite by laser sintering and conventional sintering has been investigated. The final microstructure consisted of a triphasic bioceramic after sintering.

For future work, it is suggested further developments to revolve around the laser-sintered second phase-reinforced HA (as such as HA/zirconia) composite in order to evaluate the mechanical properties.

1. Introduction

Calcium phosphate-based bioceramics have been used in medicine for 25 years because of their excellent biocompatibility, bioactivity and osteoconductive characteristics [1]. Hydroxyapatite (HA) and related calcium phosphate ceramic materials have been widely used as implant materials due to their close similarity in composition and high biocompatibility with natural bone. In view of biocompatibility, hydroxyapatite ($\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$) seems to be a suitable ceramic material for hard tissue replacement implants, it forms a direct bonding with the neighboring bones. [2]. In fact, the dense and porous HA have been vigorously investigated as implant materials for bone and tooth applications. It shows excellent biocompatibility with hard tissues and also with skin and muscle tissues [3].

Nevertheless, due to the poor mechanical properties of bulk HA ceramics, these cannot be used as implant devices to replace large bony defects or for load-bearing applications. Accordingly, there has been much effort to improve the mechanical properties of the HA. The mechanical properties of ceramics have been improved significantly by additions of strong reinforcing agents. To be used as a reinforcing agent for the HA, the biocompatibility of second phase should be considered most importantly [1].

But the number of medical applications of HA are limited, due to the rate of remodeling in the body over a long time period [4] and a relatively slow rate of osseointegration [5]. A simple method for improving the rate of remodeling of a HA implant is to introduce appreciable levels of a more resorbable calcium phosphate phase, such as tricalcium phosphate (TCP) [6]. Although HA and TCP have only slight differences in their chemical composition they differ in their biological resorbing capacity [7]. At body temperature in contact with aqueous media such as body fluids HA is a stable phase. Other phases such as TCP interact with water or body fluids at 37 °C to form HA [8]. Clinical application of pure bioactive hydroxyapatite can be improved with the bioresorbable tricalcium phosphate for better bone regeneration. The main attractive feature of bioactive bone graft materials is their ability to form a strong direct bond with the host bone resulting in a strong interface [9]. Dense HA ceramic when used as a bone implant, is almost non-resorbable and bioinert. An appropriate porosity coupled with its bioactivity provides

improved conditions for accelerated growth of the bone tissue to achieve a full integration with the living bones [7, 9].

There are 206 bones in the human body, all of which differ in size and shape from each other and vary from person to person. For reconstructive and orthopedic surgery applications the bone implant could be economically custom-made for patients by using a medical computed tomography (CT) scan. A custom-made implant of actual dimensions would reduce the time for performing the medical implantation and possible risks to the patient. Another advantage of a prefabricated and exact-fit implant is that it can be used more effectively and applied at the damage site rather than a replacement is formulated during surgery from a paste or granular material [10].

Rapid prototyping (RP) techniques can be used to fabricate dimensionally accurate prototypes of bones. RP is a relatively new technology to produce the three-dimensional (3-D) objects of complex shape directly from computer-aided design (CAD) files. RP is also known as solid freeform fabrication. The general purpose of RP is to reduce the time for product development by shortening the period between design and testing. To date the use of RP in medicine has been mainly for surgical planning and guidance with models being developed from CT or MRI data of the patient. Another useful feature of the technology is to provide a relatively simple interface to the sliced geometry from sources other than CAD solids models such as CT and MRI medical imaging equipments [11]. Solid freeform fabrication (SFF) is the prototyping of objects directly from computer models without part-specific tooling or human intervention [12]. Layer-wise slurry deposition (LSD) is an approach of SFF in which a part is built layer-wise by using slurries instead of dry powders. This process consists of three stages namely, optimization of design, slurry development, and laser sintering [13, 14, 15].

In near-net-shape forming, the principles underlying the stability of suspensions must be well understood for preparing high solid loading, stable suspensions, defect free ceramic green layers and successfully sintered layers in sequence. The objective of the project was to demonstrate the overall feasibility of using the LSD process for fabrication of near-net-shape bioceramic bone implants. The project involved several areas of effort, including formulation of a low-shrinkage bioceramic slurry system,

development and production of bioceramic layers suitable for the laser sintering process, acquisition of a computer graphic file of appropriate format (Stl) for LSD and development of LSD process parameters for making 3-D articles with the bioceramic layers.

Also aim of the present work is to analyze the influence of scan size, scan spacing and laser power on the LSD fabrication process of HA/ TCP/ amorph implant structures. This work includes the direct laser sintering process without using a binder in the slurry and comparing with conventional sintering of layers.

1.1 Stabilization of HA suspensions

The behaviour of HA aqueous suspensions is quite complex because of the changes in the concentration of the hydroxylic groups on the surface due to the suspension parameters or to the thermal treatment, as was pointed out by Galassi et al. [16].

The colloidal approach to powder processing is based on the control of the interparticle forces through the modification of the reactivity at the solid-liquid interface [17]. The spontaneously formed soft agglomerates due to van der Waals attractive forces between the powder particles are broken down into individual particles and dispersed by promoting interparticle repulsion by any or both of the following methods: (i) through the control of surface charges either by adjustment of pH of the medium or by adsorption of dispersants (electrolytes) on to the surface of powder particles (electrostatic stabilization) and (ii) through steric separation of individual particles by adsorption of neutral or charged large chain polymers on to the particle surface (steric or electrosteric stabilization) [18, 19].

The flowing properties of the slurry will be consequently tailored so as to match the rheological response required under the processing conditions. This can be achieved through the optimization of the type and quantity of the dispersing agent, solid loading, and the particle size distribution and shape of the powder particles. The optimization of colloidal suspensions is in order to reach a low viscosity and stable that is the first step in order to produce homogeneous, defect free pieces. The kind and amount of dispersant have great on the preparation of homogeneous, high concentrated ceramics suspensions with low viscosity [20, 21].

HA-based compositions are usually difficult to disperse in aqueous media, with the suspensions achieving only low or moderate solids concentrations. Nordstrom et al [22] found slip casting of the commercial HA powder to be difficult, because of the lower zeta potential values for the slip.

Toriyama et al. [23] investigated the dispersion behaviour of mechanochemically synthesized HA powders in water, using various dispersing agents. They observed that, although pH modification had a negligible effect, anionic polyelectrolytes at considerably higher concentrations (3wt%) effectively stabilized the suspensions through an electrosteric mechanism.

In this study the dispersion behaviour of HA powders in aqueous media has been investigated that it has been monitored by particle size, viscosity and zeta potential analyses as a function of pH of the slurry and the quantity of two dispersing inorganic and organic agents. It has been observed that, anionic polyelectrolytes at concentrations (0.75 wt%) effectively stabilized the suspensions through an electrosteric mechanism.

The key point at the LSD process is the preparation of a HA concentrated suspension with optimised flow behaviour [24, 25, 26]. In order to obtain the high green density and reduce the final shrinkage of components, the solids loading of the suspension must be as high as possible while the viscosity should be kept low enough for processing.

In order to obtain the dispersed slurries with high solid content it is necessary to study the different factors affecting their stability and rheology, such as the characteristics of the dispersing medium, type and amount of dispersant, powder characteristics (specific surface area, chemical composition and size distribution of the powder particles) and preparation time of slurries. The surface properties play a critical role in the dispersing behavior in water. A successful processing requires the use of well deagglomerated and relatively high concentrated suspensions. For obtaining such suspensions, the complex interfacial reactions between solvent media, dispersant, powders and additives must be taken into account. The present study is aimed at investigating the optimization of an aqueous dispersion of HA powder synthesized by powder pre-treatments. In this work the above-mentioned aspects has been studied using powders of HA calcinated at temperatures ranging between 700 and 1000 °C. Slurries with high solid content (up to 75 wt %) and good fluidity has been obtained.

1.2 Layer-wise slurry deposition (LSD) of HA

LSD is one of the established solid freeform fabrication (SFF) manufacturing processes that can build three-dimensional objects directly from computer models without part-specific tooling or human intervention. Meanwhile, there have been great efforts to develop implantable materials that can assist in regeneration of bone defects and injuries.

LSD can be used for fabrication of porous and dense ceramics and composites that it is based on layer-wise deposition of highly loaded colloidal slurries. The process is essentially binderless with less than 1% organics and layers can be fabricated, dried, and completely sintered.

These efforts include material selection, preparation of slurry, LSD process parameter optimization.

Porous HA implants have been widely used in various fields (orthopaedics, maxillofacial, etc.) and have demonstrated bone in-growth into the open pores on the surface of the implant [27]. The porosities in human bone are predominantly in the range of 1-100 μm . The canaliculi and vasculature channels are 1-5 μm in diameter. Osteocyte lacunae and Volkmann's canals are typically 5-15 μm in diameter, and the larger Haversian canals are between 50 and 100 μm in diameter. A minimum pore size of 100 μm is necessary for tissue in-growth into the bone grafts to maintain blood supply in the connective tissues. As the bone cells grow within the interconnected pore channels, the implant serves as a structural bridge or scaffold for bone formation. A pore size of approximately 100-150 μm has been established as necessary, but interconnectivity is more critical than the pore size. Macroporous scaffolds based on ceramics and glass-ceramics have been produced by several techniques such as the use of polymeric sponge, foaming process. Synthetic HA for bone substitution can be produced with a range of porosities depending on the method of processing. The porosity can be classified according to pore diameter as macroporosity ($>10\mu$) and microporosity ($<10\mu$) and it has been suggested that these structural modifications influence the biocompatibility of HA [28].

Laser sintering of oxide ceramics is a fast process because the oxides effectively absorb CO_2 laser radiation [29].

The microstructure and composition evolution during the laser sintering and conventional sintering are also a subject for this work.

1.3 LSD of HA-glass composite

In order to increase the mechanical strength of HA, a variety of processing techniques have been developed. Knowles et al. reported that mechanical properties of unmodified HA can be improved significantly by adding a small amount of CaO-P₂O₅-Na₂O-based sintering additives [30].

The chemical analysis of the inorganic part of bone is complex because of ion substitution that may occur in hydroxyapatite lattice, where CO₃²⁻ is a common substitute for OH⁻ or PO₄³⁻, Mg²⁺ and Na⁺ for Ca²⁺, and F⁻ for OH⁻. Therefore, there is a need to include these trace elements in the HA used for implants and prostheses, since the biological behaviour of apatites is strongly dependent on their composition. Using glasses within the P₂O₅-CaO system with additions of Na⁺, Mg²⁺, and K⁺ ions, glass-reinforced HA composites can be prepared by a liquid-phase sintering process, with much higher biaxial bending strength than commercial sintered HA [31]. It has been speculated that the flexural bending of these composites is related to some microstructural characteristics such as the presence of secondary phase, β and α -TCP and the percentage of porosity in the microstructures. In vivo performance of this composite plays a vital role in the integrity and the function of bone and soft connective tissues. Lopes et al. confirmed that toughness and hardness of glass reinforced HA composite are highly depended on microstructural characteristic [32].

Calcium phosphate bioceramics can be used in applications where bone ingrowth is intended. In this application, the ideal material is the one with a degradation ratio similar to that of new bone formation. It is well established that pure and crystalline hydroxyapatite has a low degradation ratio in vivo. For this reason, recent studies have pointed to the design of multiphasic calcium phosphate bioceramics as bone fillers [33]. These materials contain other calcium phosphates with higher solubility when compared to pure hydroxyapatite. Tricalcium phosphates are bioactive ceramics that can be associated to hydroxyapatite. These bioceramics exhibit polymorphism: α -TCP and β -TCP. In temperatures above 1300 °C, β -TCP is likely to decompose in α -TCP [34].

In this study, the fabrication of the dense and porous glass- HA composite by laser sintering and conventional sintering has been investigated. The final microstructure consisted of a triphasic bioceramic after sintering.

2 Literature survey

2.1 Overview on rapid prototyping

The term rapid prototyping (RP) refers to a class of technologies that can automatically construct physical models from computer-aided design (CAD) data. These "three dimensional printers" allow designers to quickly create tangible prototypes of their designs, rather than just two-dimensional pictures. Prototypes are also useful for testing a design that it is as desired or needs improvement. For designers RP allows them to be made faster and less expensively [35, 36].

RP techniques can also be used to make tooling (referred to as rapid tooling) and even production-quality parts (rapid manufacturing). For small production runs and complicated objects, rapid prototyping is often the best manufacturing process available. Of course, "rapid" is a relative term. Most prototypes require from three to seventy-two hours to build, depending on the size and complexity of the object. This may seem slow, but it is much faster than the weeks or months required to make a prototype by traditional means such as machining. These dramatic time savings allow manufacturers to bring products to market faster and more cheaply [35].

At least six different rapid prototyping techniques are commercially available. Because RP technologies are being increasingly used in non-prototyping applications, the techniques are often collectively referred to as *solid free-form fabrication*, *computer automated manufacturing*, or *layered manufacturing*. The latter term is particularly descriptive of the manufacturing process used by all commercial techniques. A software package "slices" the CAD model into a number of thin (~ 0.1 mm) layers, which are then built up one atop another. Rapid prototyping is an "additive" process, combining layers of paper, wax, or plastic to create a solid object. In contrast, most machining processes (milling, drilling, grinding, etc.) are "subtractive" processes that remove material from a solid block. RP's additive nature allows it to create objects with complicated internal features that cannot be manufactured by other means [35, 37].

Rapid prototyping is widely used in the automotive, aerospace, medical, and consumer products industries. Part volume is generally limited to 0.125 cubic meters or less, depending on the RP machine. Mechanical performance of the fabricated parts is limited by the materials

that must be used in the RP process. Ceramic and metal prototypes are difficult to make, though this should change in the near future.

Although several rapid prototyping techniques exist, all employ the same basic five-step process. The steps are:

1. Create a CAD model of the design
2. Convert the CAD model to STL format
3. Slice the STL file into thin cross-sectional layers
4. Construct the model one layer atop another
5. Clean and finish the model

2.1.1 Rapid prototyping technologies

There are various ways to classify the RP techniques that have currently been developed. The RP classification used here is based on the form of the starting material. Most commercially available rapid prototyping machines use one of six techniques [35].

- *Liquid-based rapid prototyping systems:* Starting material is a liquid.

Stereolithography and solid ground curing systems are described here.

- *Solid-based rapid prototyping systems:* Starting material is a solid.

Laminated object manufacturing and fused deposition modeling systems are presented here.

- *Powder-based rapid prototyping systems:* Starting material is a powder.

Selective laser sintering and three dimensional printing systems are described here.

2.1.1a Stereolithography

Patented in 1986, stereolithography started the rapid prototyping revolution. The technique builds three-dimensional models from liquid photosensitive polymers that solidify when exposed to ultraviolet light. As shown in Fig. 1.2, the model is built upon a platform situated just below the surface in a vat of liquid epoxy or acrylate resin. A low-power highly focused UV laser traces out the first layer, solidifying the model's cross section while leaving excess areas liquid [38].

Next, an elevator incrementally lowers the platform into the liquid polymer. A sweeper re-coats the solidified layer with liquid, and the laser traces the second layer atop the first. This

process is repeated until the prototype is complete. Afterwards, the solid part is removed from the vat and rinsed clean of excess liquid. Supports are broken off and the model is then placed in an ultraviolet oven for complete curing [38].

Figure 1.2 Schematic diagram of stereolithography [38].

2.1.1b Solid ground curing

Developed by Cubital, solid ground curing (SGC) is somewhat similar to SLA in that both use ultraviolet light to selectively harden photosensitive polymers. Fig. 2.2 shows schematic diagram of SGC process. First, photosensitive resin is sprayed on the build platform. Next, the machine develops a photomask (like a stencil) of the layer to be built. This photomask is printed on a glass plate above the build platform using an electrostatic process similar to that found in photocopiers. The mask is then exposed to UV light, which only passes through the transparent portions of the mask to selectively harden the shape of the current layer.

Fig. 2. 2 Schematic diagram of solid ground curing [38].

After the layer is cured, the machine vacuums up the excess liquid resin and sprays wax in its place to support the model during the build. The top surface is milled flat, and then the process repeats to build the next layer. When the part is complete, it must be de-waxed by immersing it in a solvent bath. The sequence for each layer takes about 90 seconds. Time to produce a part by SGC is claimed to be about eight times faster than other RP systems and can produce large models [38, 39].

2.1.1c Laminated object manufacturing

Laminated object manufacturing (LOM) was developed in 1985 and commercialised by Helisys Corporation in the USA to build components with layers of paper or plastic [38].

The original material consists of paper laminated with heat-activated glue and rolled up on spools. As shown in Fig. 3.2 a focused laser cuts the outline of the first layer into the paper and then cross-hatches the excess area (the negative space in the prototype). During the build, the excess material provides excellent support for overhangs and thin-walled sections. After the first layer is cut, the platform lowers out of the way and fresh material is advanced. The platform rises to slightly below the previous height, the roller bonds the second layer to the first, and the laser cuts the second layer. This process is repeated as needed to build the part, which will have a wood-like texture. Because the models are made of paper, they must be sealed and finished with paint or varnish to prevent moisture damage. Helisys developed several new sheet materials, including plastic, water-repellent paper, and ceramic and metal powder tapes. The powder tapes produce a "green" part that must be sintered for maximum strength [38].

Fig. 3.2 Schematic diagram of laminated object manufacturing [38].

2.1.1d Fused deposition modeling

In this technique, filaments of heated thermoplastic are extruded from a tip that moves in the x-y plane. Like a baker decorating a cake, the controlled extrusion head deposits very thin beads of material onto the build platform to form the first layer. The platform is maintained at a lower temperature, so that the thermoplastic quickly hardens. After the platform lowers, the extrusion head deposits a second layer upon the first. Supports are built along the way, fastened to the part either with a second, weaker material or with a perforated junction [35, 38]. Fig. 4.2 shows schematic diagram of FDM.

Fig. 4.2 Schematic diagram of fused deposition modelling [35].

2.1.1e Selective laser sintering

Developed by Carl Deckard at the University of Texas, selective laser sintering was patented in 1989 [38]. The technique, shown in Fig. 5.2, uses a laser beam to selectively fuse powdered materials, such as nylon, elastomer, and metal, into a solid object. Parts are built upon a platform which sits just below the surface in a bin of the heat-fusible powder. The platform is lowered by the height of the next layer and powder is reapplied. This process continues until the part is completed. Excess powder in each layer helps to support the part during the build.

Parts processed by SLS are often porous and post processing is necessary when strength is required in ceramic parts. Conventional sintering and hot isostatic pressing are two common

methods used to increase final density. No support structure is needed as the non-fused powder remains in place to act as a support itself [38, 40].

Fig. 5.2 Schematic diagram of selective laser sintering [35].

2.1.1f 3-D Ink-jet printing

Three-dimensional printing (3DP) was developed at MIT in 1992 as a method to create performs from powdered metals and ceramics [38]. As shown in Fig. 6.2, parts are built upon a platform situated in a bin full of powder material. An ink-jet printing head selectively deposits or "prints" a binder fluid to fuse the powder together in the desired areas. Unbound powder remains to support the part. The platform is lowered, more powder added and leveled, and the process repeated.

Fig. 6.2 Three dimensional printing: (1) powder layer is deposited, (2) ink-jet printing of areas that will become the part, and (3) piston is lowered for next layer (key: v = motion) [38].

When finished, the green part is then removed from the unbound powder, and excess unbound powder is blown off. Finished parts can be infiltrated with wax or other sealants to improve durability and surface finish. Typical layer thicknesses are on the order of 0.1 mm. This process is very fast, and produces parts with a slightly grainy surface. This yields extremely good accuracy, allowing the machines to be used in the jewelry industry. Three-dimensional printing does not require high energy, does not involve lasers or any toxic materials and is relatively cheap and fast [38, 40].

2.1.2 Introduction to laser materials processing

The first laser is attributed to Theodore Maiman, who successfully excited a ruby crystal to emit light in 1960 [41]. Since the late 1960 s, the CO₂ laser has been the workhorse in various industrial materials processing applications. Over the past decade, the neodymium ion-doped yttrium aluminum garnet (Nd: YAG) solid-state lasers have become increasingly popular for manufacturing applications, due to better absorptivity and the ability to use fiber optics for beam transport.

There is a straightforward approach to understanding laser processing which is relevant for every situation. This approach considers the only processes that can occur when a laser beam strikes a surface. A laser or any light beam, is either reflected or absorbed or transmitted. Expressed very simply: $\text{Reflection} + \text{Absorption} + \text{Transmission} = 1$

In almost all practical situations, some or all three processes occur. Furthermore, considering the relative amounts of each of these processes that occur to be also useful in a particular process. The next assumption in almost practical situations, some of the photons are absorbed by the target and these photons are converted into thermal energy at the target, heat, that it may be either conducted, radiated or convected away from the area. But conduction is the dominating process. If the rate of heat input to the target zone is greater than the rate of conduction of heat away from the target zone, then the temperature rises locally and either melting or vaporization or a combination of both occurs [41].

A significant proportion of the beam is absorbed by the target, as this is usually the case in the majority of industrial laser processes. It is widely accepted that there are three dominating factors:

- average power of the laser beam

- intensity of the laser spot on the target
- wavelength of the laser beam.

Of these three, perhaps the average power in watts is the easiest to understand and the intensity and wavelength need some explanation. Intensity (or irradiance), is usually calculated approximately by dividing the power of the beam by the spot area. For a fixed wavelength, the laws of physics tell us that all the photons have the same energy. For a shorter wavelength beam, the energy of each photon is higher. This initial reaction may be then sustained or not sustained according to the heat input or average power in watts (W) of the laser beam. The average power of a laser beam is very easy to understand and measure, especially for a continuous wave (CW) beam. For a pulsed beam, the product of the pulse energy and the pulse repetition rate gives us the average power [41].

When this stream of pure light or photons are absorbed by a surface, usually, the energy is converted into vibration of the atoms which in effect heats up the surface, although in some cases this can be on the scale of a few thousandths of a millimeter (or microns) when energy of photons is high enough. Under certain very special conditions these photons may break an atomic bond. The majority of laser processes are however, thermal in nature, they are the result of the generation of controlled melting and vaporization processes. There are two other generalizations which may also help: we may visualize the wavelength of the laser beam and the intensity of the laser spot on the target as controlling the initial reaction of the target to the beam and the average power as determining the rate of the process [41].

Fig. 7.2 shows schematically the interaction of a laser beam with a structure. Assuming a reasonable degree of absorption (with ignore transmission), the incident photons are absorbed either due to excitation of electrons or for longer wavelengths, excitation of vibrational modes.

The desirable wavelengths for optimum energy absorption for reflective alloys include visible end (511 nm) to near-infrared (1.06 μm) wavelengths as found in solid-state lasers. Fig. 8.2 shows absorption curve of various lasers by metals, insulators.

In metals, absorption takes place very near the surface and can occur by excitation of both conduction band (free electron-like) and valance band (interband absorption) electrons are the absorbing entities. These electrons transfer their increased kinetic energy to the lattice via phonon scattering on time scales of ps, resulting in a temperature increase. For long pulses (> ps) heating is occurring during the pulse and so in general one can treat light energy to heat in

one step. For semiconductors and insulators, absorption is either through vibrational excitation (requiring infrared light matching allowed vibrational transitions of the material) or electronic excitations (e.g., via chromophores, defects, or band-to-band transitions). The practical use of lasers in fabrication is dominated by thermal processes thus arguing over “photoelectronic” vs. “photothermal” is moot [27, 41].

Fig. 7.2 Schematic of relevant interactions and consequences of energy absorption [41].

Fig. 8.2 Absorbion curve of various lasers by metals, insulators [27].

2.2 Colloidal processing of ceramics

The term "colloid" is used to describe particles that possess at least one dimension in the size range 1 to 1000 nm [42].

Colloidal processing of ceramics is reviewed with an emphasis on interparticle forces and suspension rheology.

2.2.1 Interparticle forces

Through careful control of interparticle forces, colloidal suspensions can be prepared in the dispersed, weakly flocculated, or strongly flocculated states, as shown schematically in Fig. 9. 2. In the dispersed state, discrete particles that exist in the suspension repel one another on close approach, provided the repulsive barrier is $\gg k_b T$. In the weakly flocculated state, particles aggregate in a shallow secondary minimum (well depth $\approx 2-20 k_b T$), forming isolated clusters (or flocs) in suspension at volume fractions below the gel point ($\phi < \phi_{gel}$) or a particle network at higher volume fractions ($\phi \geq \phi_{gel}$). In this case, an equilibrium separation distance exists between aggregated particles. In contrast, particles aggregate into a deep primary minimum in the strongly flocculated (or coagulated) state, forming either a touching particle network or individual clusters in suspension, depending on their concentration.

Colloidal stability is governed by the total interparticle potential energy, V_{total} , which can be expressed as

$$V_{total} = V_{vdW} + V_{elect} + V_{Steric} + V_{Structural} \quad (1)$$

where V_{vdW} is the attractive potential energy due to long-range van der Waals interactions between particles, V_{elect} the repulsive potential energy resulting from electrostatic interactions between like-charged particle surfaces, V_{steric} the repulsive potential energy resulting from steric interactions between particle surfaces coated with adsorbed polymeric species, and $V_{structural}$ the potential energy resulting from the presence of nonadsorbed species in solution that may either increase or decrease suspension stability [42, 43].

2.2.2 Van der Waals attractive forces

Long-range forces resulting from van der Waals (vdW) interactions are ubiquitous and always attractive between like particles.

Fig. 9.2 Schematic illustration of the relationship between the total interparticle potential energy and the resulting suspension structure. (Ordinate axis is generally scaled to kT ; i.e., energy resulting from thermal fluctuations) [43].

V_{vdW} exhibits a power-law distance dependence whose strength depends on the dielectric properties of the interacting colloidal particles and intervening medium. For spherical particles of equal size, V_{vdW} is given by the Hamaker expression:

$$V_{vdW} = -\frac{A}{6} \left(\frac{2}{s^2 - 4} + \frac{2}{s^2} + \ln \frac{s^2 - 4}{s^2} \right) \quad (2)$$

where s is

$$s = \frac{2a + h}{a} \quad (3)$$

and where h is the minimum separation between the particle surfaces, a the particle radius, and A the Hamaker constant. Long-range attractive vdW forces between particles must be mitigated during colloidal processing to achieve the desired degree of suspension stability [43].

2.2.3 Electrostatic forces (Electrical double layer stabilization)

The stability of aqueous colloidal systems can be controlled by generating like-charges of sufficient magnitude on the surfaces of suspended ceramic particles. The resulting repulsive V_{elect} exhibits an exponential distance dependence whose strength depends on the surface potential induced on the interacting colloidal particles and the dielectric properties of the intervening medium. Exact analytical expressions for the electrostatic potential energy cannot be given; therefore, analytical approximations or numerical solutions are used. For spherical particles of equal size that approach one another under conditions of constant potential, V_{elect} is given by

$$V_{\text{elect}} = 2\pi\epsilon_r\epsilon_0a\Psi_0^2 \ln[1 + \exp(-\kappa h)] \quad (4)$$

provided ka is sufficiently large (>10). In contrast, when the double layer around each particle is extensive ($ka < 5$), V_{elect} is given by

$$V_{\text{elect}} = 2\pi\epsilon_r\epsilon_0a\Psi_0^2 \exp(-\kappa h) \quad (5)$$

where ϵ_r is the dielectric constant of the solvent, ϵ_0 the permittivity of vacuum, ψ_0 the surface potential, and $1/k$ the Debye-Hückel screening length. k is given by

$$\kappa = \left(\frac{F^2 \sum_i N_i z_i^2}{\epsilon_r \epsilon_0 kT} \right)^{1/2} \quad (6)$$

where N_i and z_i are the number density and valence of the counterions of type i , and F the Faraday constant. ψ_0 results from the dissociation of amphoteric hydroxyl groups present on oxide surfaces and depends on pH and indifferent electrolyte concentration. It can be estimated from the zeta potential (ξ), which measures the electrostatic potential at, or very near to, the beginning of the diffuse double layer [42, 43].

2.2.4 Polymeric stabilization

The spatial extension of polymer molecules of even modest molecular weights is usually comparable to the range of the London attraction between colloidal particles and of course greater than the range of van der Waals force and it can generate repulsion. There is a

minimum thickness of a polymer layer at the particles surface for stabilization. The minimum depends on the particle size and the magnitude of the Hamaker constant. One major advantage of macromolecules is that their dimensions are relatively insensitive to electrolyte concentration, unlike electrical double layers. In addition, polymeric stabilization can be more powerful than electrostatic stabilization, providing stability for a longer time and at high solids loading. When flocculation or phase separation does occur, it is normally reversible, a suitable change in the solvent conditions will redisperse the particles spontaneously. There are at present two different mechanisms whereby polymer chains can impart colloid stability: steric stabilization and depletion stabilization [43].

2.2.4a Steric stabilization

Steric stabilization of colloidal particles is produced by macromolecules that are attached (e.g. by grafting or by physical adsorption) to the surfaces of the particles (Fig. 10. 2a). If enough polymer adsorbs, the thickness of the coating is sufficient to keep particles separated by steric repulsion between the polymer layers, and at those separations the van der Waals forces are too weak to cause the particles to adhere. This is presented schematically in Figure 10. 2a. For small particles, Brownian motion is then sufficient to keep them suspended indefinitely. The steric repulsion can be regarded as a loss in configuration entropy that occurs when polymer chains of two particles interpenetrate. This produces an increase in the free energy of the system. The positive ΔG for polymer chain interpenetration which leads to steric stabilization is given in terms of the corresponding enthalpy and entropy changes by $\Delta G = \Delta H - T\Delta S$, and therefore, stabilization could be the result of a positive ΔH and/or a negative ΔS . A positive ΔH would reflect the release of bound solvent from the polymer chains as they interpenetrate and a negative ΔS would reflect loss of configurational freedom as the polymer chains interpenetrate. If ΔH is positive and/or ΔS negative, the dispersion will be sterically stabilized at all accessible temperatures. However, if ΔH and ΔS are both positive, the dispersion should flocculate on heating (enthalpic stabilization), whereas if ΔH and ΔS are both negative, the dispersion should flocculate on cooling below the theta-temperature (entropic stabilization) [43].

The interactions between particles for steric stabilization have not been quantified. To describe the magnitude and range of the interaction between polymer layers, the solution properties of the polymer and the conformations of the polymer at the solid-liquid interface need to be considered [44].

Fig. 10.2 Schematic representation of (a) steric and (b) depletion stabilization [44]

2.2.4b Depletion stabilization

Depletion stabilization differs from steric stabilization in that the stability is imparted not by attached polymers but by macromolecules that are free in solution (Fig. 10.2b). An approach of the particles is accompanied by demixing of the polymer molecules and the solvent in the interparticle region. This process needs a force to extrude polymer out of the interparticle region. It corresponds to a repulsion between the particles that can lead to stabilization of the suspension [45].

2.2.4c Combinations of stabilization methods (Electrosteric forces)

It is possible to combine electrostatic and steric stabilization, what has been termed electrosteric stabilization. The electrostatic component is supposed to originate from a net charge on the particle surface (Fig. 11.2a) and/or charges associated with the polymer attached to the surface (i.e. through an attached polyelectrolyte) (Fig. 11.2b).

Fig. 11.2 Schematic representation of electrosteric stabilization: (a) charged particles in combination with nonionic polymers and (b) polyelectrolytes attached to uncharged particles [44].

Electrosteric stabilization is common in biological systems. In addition to electrosteric stabilization, it is possible to have combinations of depletion stabilization with both steric and/or electrostatic stabilization. The combination of depletion and steric stabilization is quite common at high concentrations of free polymer in the dispersion medium [44, 45].

2.3 Suspension rheology

The rheological behavior of colloidal dispersions is among their most important properties. Rheological measurements monitor changes in flow behavior in response to an applied stress (or strain) [46].

In viscous flow behaviour, the apparent viscosity (η) is related to the applied shear stress (τ) and shear rate $\dot{\gamma}$ by the following expression:

$$\tau = \eta \dot{\gamma} \quad (9)$$

Various types of flow behaviour can be observed under steady shear depending on suspension composition and stability, as shown in Fig. 12.2. Newtonian behavior is the simplest flow response, where viscosity is independent of shear rate (see curve (a) in Fig. 12.2). Pseudoplastic or shear-thinning behaviour occurs when the viscosity decreases with shear rate (see curve (b)). This response can be accompanied by a yield stress whose magnitude depends on the strength of the particle network (see curves (d) and (e)). If the flow curve is linear above τ_y , the system is referred to as Bingham plastic (curve (d)).

Fig. 12.2 Types of rheological behavior exhibited by colloidal dispersions: (a) Newtonian flow; (b) shear thinning; (c) shear thickening; (d) Bingham plastic; and (e) pseudoplastic with a yield stress [46].

Finally, dilatent or shear-thickening behaviour occurs when the viscosity increases with shear rate (see curve (c)). The rheological properties of concentrated colloidal suspensions are often time dependent. Thixotropic systems exhibit an apparent viscosity that decreases with time under shear, but recovers to its original viscosity when flow ceases. The opposite behaviour is referred to as rheopexy [46].

2.4 The drying behaviour of the bodies (consolidation via fluid removal)

In slip casting, for example, the fluid flows into a porous gypsum mould via capillary-driven transport phenomena. The fluid is supplied via capillary-driven transport to the external surface(s) of the component, where evaporation takes place. As drying proceeds, large pores drain as the fluid is drawn to the smaller pores with higher suction potential. The drained pores may penetrate far into the component interior, provided the rate of capillary redistribution of fluid exceeds the evaporation rate. During drying, the transport of liquid through a porous medium is governed by the pressure gradient resulting from the capillary pressure P_{cap} :

$$P_{cap} = \frac{2\gamma_{LV}}{r_p} \quad (10)$$

where γ_{LV} is the liquid-vapor surface tension and r_p is pore size, which can be approximated by the hydraulic radius, r_h :

$$r_h = \frac{2(1-\phi)}{A_s \phi \rho} \quad (11)$$

where, ϕ is volume fraction of colloidal particles in suspension and A_s and ρ are specific surface area of particles and density of solution, respectively.

In accordance with Darcy's law, the liquid flux (J) is proportional to the pressure gradient in the liquid, $\partial P / \partial x$:

$$J = \frac{D}{\eta_0} \frac{\partial P}{\partial x} \quad (12)$$

where, η_0 is the solution viscosity and D is the permeability given by

$$D = \frac{(1-\phi)^3}{5(A_s \phi \rho_s)^2} \quad (13)$$

The length scale (l_{cap}) over which capillary migration occurs during drying has been derived previously:

$$l_{cap} = \left[\frac{2H(\Delta P)(1-\phi)^3}{5V_E \eta_0 (A_s \phi_s)^2} \right]^{1/2} \quad (14)$$

where H is the layer thickness, V_E is the evaporation rate, ρ_s is density of colloidal particles and ΔP is the pressure drop estimated from Eq (10). The importance of capillary-driven liquid migration is shown by comparing l_{cap} to the characteristic size of the drying layer (or body) H . When $l_{cap} > H$, the liquid-vapor interface penetrates into the layer as an irregular front. In contrast, when $l_{cap} \ll H$, the liquid-vapor interface penetrates into the body as a planar front. This latter situation should be avoided, because it leads to a sharp stress gradient that promotes cracking. As shown in Eq (14), l_{cap} can be increased by decreasing the drying rate V_E , increasing the initial solids loading in suspension, or decreasing the fluid viscosity [47, 48].

2.5 Introduction to bioceramics

Revolution has occurred in the use of ceramics during the past four decades to improve the quality of life. The development of advanced materials for biomedical applications is among the most important problems facing modern materials engineering. This revolution is the innovative use of specially designed ceramics for the repair, reconstruction, and replacement of diseased or damaged parts of the body. Ceramics used for this purpose are termed “bioceramics” [49].

2.5.1 Bioceramic types and their properties

The class of ceramics used for repair and replacement of diseased and damaged parts of musculoskeletal systems are termed bioceramics. Bioceramics have become a diverse class of biomaterials presently including three basic types: bioinert high strength ceramics, bioactive ceramics which form direct chemical bonds with bone or even with soft tissue of a living organism; various bioresorbable ceramics that actively participate in the metabolic processes of an organism with the predictable results [1]. Alumina (Al_2O_3), zirconia (ZrO_2) and carbon are termed bioinert. HA and bioglass are bioactive. Calcium phosphate ceramics are categorized as bioresorbable. Bioceramics became an accepted group of materials for medical

applications, mainly for implants in orthopaedics, maxillofacial surgery and for dental implants [49].

Applications include replacements for hips, knees, teeth, tendons, and ligaments and repair for periodontal disease, maxillofacial reconstruction, augmentation and stabilization of the jaw bone, spinal fusion, and bone repair after tumor surgery. Clinical success of bioceramics has led to a remarkable advance in the quality of life for millions of people. The mechanisms of tissue bonding to bioactive ceramics have resulted in the molecular design of bioceramics for interfacial bonding with hard and soft tissue. This review is devoted to the use of bioceramics as implants to repair parts of the body, usually the hard tissues of the musculo-skeletal system, such as bones, joints, or teeth [2].

Resorbable biomaterials are designed to degrade gradually over time and be replaced by the natural host tissue. Porous or particulate calcium phosphate ceramic materials, such as tricalcium phosphate (TCP), are successful materials for resorbable, hard tissue replacements when only low mechanical strength is required, such as in some repairs of the jaw or head [50, 51]. The concept of bioactive materials is intermediate between resorbable and bioinert materials. A bioactive material is one that elicits a specific biological response at the interface of the material, which results in the formation of a bond between the tissues and the material. This concept has been used to produce many bioactive materials with a wide range of bonding rates and thickness of interfacial bonding layers. All the bioactive materials form an interfacial bond with adjacent tissue. However, the time dependence of bonding, the strength of the bond, the mechanism of bonding, and the thickness of the bonding zone differ for the various materials. Porous layer is accelerated by the bioactive HA ceramic, and the strength of the bone–implant interface also is enhanced. Thus, bone bonding and biological fixation are restricted to specific areas, which reduces stress shielding in other areas of bone contact [2].

2.5.2 Calcium phosphate ceramics types

Calcium phosphate-based bioceramics have been used in medicine and dentistry for 25 years. Calcium phosphate (CaP) bioceramics in different forms (blocks, granules, cements, implant coatings, composite component), from different origin (natural, biological or synthetic) and varying composition are commercially available for use in dentistry and medicine. Calcium phosphate compounds are abundant in nature and in living systems. Different types of calcium phosphate (CaP) phases play dominant and significant role in biological systems [52]. Table 1.2 show calcium phosphates types arranged by Ca: P ratio.

Table 1.2 Calcium phosphates types arranged by Ca: P ratio [52].

Ca/P ratio	Compound	Formula
0.5	Monocalciumphosphate monohydrate(MCPM)	$\text{Ca}(\text{H}_2\text{PO}_4)_2 \cdot \text{H}_2\text{O}$
0.5	Monocalcium phosphate anhydrous (MCPA)	$\text{Ca}(\text{H}_2\text{PO}_4)_2$
1	Dicalcium phosphate dihydrate (DCPD)	$\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$
1	Dicalcium phosphate anhydrous (DCPA)	CaHPO_4
1.33	Octacalcium phosphate (OCP)	$\text{Ca}_8(\text{H}_2\text{PO}_4)_2(\text{PO}_4)_4 \cdot 5\text{H}_2\text{O}$
1.5	Amorphous calcium phosphate (ACP)	$\text{Ca}_3(\text{PO}_4)_2 \cdot x\text{H}_2\text{O}$
1.5	α -Tricalcium phosphate (α -TCP)	$\alpha\text{-Ca}_3(\text{PO}_4)_2$
1.5	β -Tricalcium phosphate (β -TCP)	$\beta\text{-Ca}_3(\text{PO}_4)_2$
1.67	Hydroxyapatite (HA)	$\text{Ca}_5(\text{PO}_4)_3(\text{OH})$
2.0	Tetracalcium phosphate (C_4P)	$\text{Ca}_4\text{P}_2\text{O}_9$

β -tricalcium phosphate (β -TCP) is represented by the chemical formula $\text{Ca}_3(\text{PO}_4)_2$, the Ca/P ratio being 1.5. β -TCP shows an X-ray pattern consistent with a pure hexagonal crystal structure, although the related α -TCP is monoclinic. Single-phase TCP powders have also been synthesized successfully by many researchers. β -TCP turns into α -TCP around 1200°C; the latter phase is considered to be stable in the range 700 to 1200 °C. β -TCP is highly soluble in body fluid. HA is formed on exposed surfaces of TCP by the following reaction.

Thus, the solubility of a TCP surface approaches the solubility of HA and decreases the pH of the solution, which further increases the solubility of TCP and enhances resorption. Many studies have indicated that the dissolution of HA in the human body after implantation is too low to achieve the optimal results. On the other hand, the dissolution rate of β -TCP ceramic is too fast for bone bonding. To achieve an optimum resorbability of the material, studies have mainly focused on the biphasic calcium phosphate ceramics composed of HA and TCP. Several results suggest that the resorbability of biphasic ceramics is largely determined by the HA / TCP ratio. Also, the osteoinductive potential varies in different materials. Bone formation was only seen in calcium phosphate biomaterials with micropores and was found in HA ceramic, TCP / HA, β -TCP ceramic and calcium phosphate cement [49].

2.5.3 Properties and applications of calcium phosphate bioceramics

The many desirable properties of calcium phosphate bioceramics have been documented. These properties include similarity in composition to bone mineral; bioactivity (ability to form bone apatite-like on their surfaces in vitro and ability to develop a direct and strong bonding with the bone tissue); biocompatibility (ability to promote cellular function and ability to form a uniquely strong interface with bone) and osteoconductivity (ability to provide a scaffold or template for the formation of new bone). In addition, calcium phosphate ceramics with the appropriate three-dimensional geometry, are able to bind and concentrate bone morphogenic proteins in circulation and thus become osteoinductive (capable of osteogenesis). Potential future applications of calcium phosphate bioceramics will include drug delivery system, growth factor carriers, effective carriers of bioactive peptide or bone cells, periodontal ligament cells, mesenchymal cells and will therefore be useful in tissue engineering for regeneration of hard tissues [53].

Applications include coatings of orthopedic and dental implants, alveolar ridge augmentation, maxillofacial surgery, otolaryngology, and scaffolds for bone growth and as powders in total hip and knee surgery. Different phases of calcium phosphate ceramics are used depending upon whether a resorbable or bioactive material is desired. The stable phases of calcium phosphate ceramics depend considerably upon temperature and the presence of water, either during processing or in the use environment. At body temperature, only two calcium phosphates are stable in contact with aqueous media, such as body fluids: at pH <4.2, the stable phase is $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$ (dicalcium phosphate, brushite, C_2P), whereas, at pH >4.2, the stable phase is $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$ (HA). At higher temperatures, other phases, such as $\text{Ca}_3(\text{PO}_4)_2$ (β -tricalcium phosphate, C_3P , TCP) and $\text{Ca}_4\text{P}_2\text{O}_9$ (tetracalcium phosphate, C_4P) are present. The unhydrated, high-temperature calcium phosphate phases interact with water, or body fluids, at 37 °C to form HA. Thus, the solubility of a TCP surface approaches the solubility of HA and decreases the pH of the solution, which further increases the solubility of TCP and enhances resorption [53]. De Groot [50] has discussed the importance of the Ca: P ratio in determining solubility and tendency for resorption in the body. The presence of micropores in the sintered material can increase the solubility of these phases.

Sintering of calcium phosphate ceramics usually occurs at 1000–1500 °C, following compaction of the powder into a desired shape. The phases formed at high temperature depend on temperature and on the partial pressure of water ($\text{P}_{\text{H}_2\text{O}}$) in the sintering atmosphere. When water is present, HA can be formed and is a stable phase up to 1360 °C, as shown in the

phase equilibrium diagram for CaO and P_2O_5 with 500 mmHg (66 kPa) P_{H_2O} (Fig. 13.2). When there is no water, C_4P and C_3P are the stable phases. The temperature range of HA stability increases with P_{H_2O} , as does the rate of phase transitions of C_3P or C_4P to HA. Because of kinetics barriers that affect the rates of formation of the stable calcium phosphate phases, it often is difficult to predict the volume fraction of high-temperature phases that are formed during sintering and their relative stability when cooled to room temperature [3, 53].

The mechanical behaviour of calcium phosphate ceramics strongly influences their application as implants. Tensile and compressive strength and fatigue resistance depend on the total volume of porosity. Porosity can be in the form of micropores (<1 mm diameter, due to incomplete sintering) or macropores (>100 mm diameter, created to permit bone growth). The weibull modulus of HA implants is low in physiological solutions, which indicates low reliability under tensile loads. Consequently, in clinical practice, calcium phosphate bioceramics should be used as powders; small, unloaded implants; dental implants (with reinforcing metal posts); coatings on metal implants; low-loaded porous implants (where bone growth acts as a reinforcing phase); or bioactive phase in a polymer–bioactive ceramic composite. The bonding mechanisms of dense HA implants appear to differ from bioactive glasses [2, 49, 53].

Fig. 13.2 Calcium phosphate phase equilibrium diagram with 500 mmHg P_{H_2O} [3].

2.5.4. HA-based ceramics

The greatest potential for bone substitution is shown by materials based on hydroxyapatite (HA), which can develop tight bonding with bone tissue, exhibits osteoconductive behaviour, is stable toward bioresorption, and has no adverse effects on the human organism [53, 54]. The biological behavior of HA ceramics depends on many factors, in particular, on their chemical and phase composition, microstructure, pore size, and pore volume. In surgery has been used of both dense and porous ceramics, depending on the requirements for the bearing strength of implants. Porous ceramics have low strength and therefore are suitable for implantation into tissues which experience no substantial stresses (operations for the middle ear and some maxillofacial applications) and for local drug delivery. Pores in implants are necessary for osteointegration, a process which depends on the pore size, volume, and interconnectivity [55, 56].

It is believed that the minimum pore size for bone ingrowth into implants is 100–135 μm . With increasing porosity and pore interconnectivity, the bone ingrowth and fixation processes become more effective. The division of osteogenic cells is preceded by protein adsorption. Consequently, the presence of submicron pores, comparable in size to blood-plasma proteins must also favor biointegration [57].

2.5.5 Synthesis and properties of HA

HA powder can be prepared wet chemically, by solid-state reactions, and by hydrothermal treatment. The preparation technique has a significant effect on the powder morphology, specific surface, stoichiometry, and crystallinity. Therefore, control over all synthesis conditions is critical for obtaining reproducible results [58].

HA belongs to the apatite group and has the composition $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$. The structure of fluorapatite, a analog of HA, was first determined by Náray- Szabó. His works laid the foundation for subsequent X-ray diffraction studies of HA, fluorapatite and chlorapatite. His conclusions about the structure of fluorapatite were confirmed by later refinements. HA has a hexagonal structure ($P6\ 3/m$, two formula units per unit cell) with lattice parameters $a = 0.942$ nm and $c = 0.687$ nm. The ideal formula of HA is $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$. The atomic structure of HA and its projection along the c axis are shown in Fig. 14.2. The Ca atoms reside in two positions: six atoms per unit cell are in position Ca (II) and four atoms are in position Ca (I). Ca (I) is located on the threefold axis and is coordinated by nine oxygens of phosphate

groups. The Ca (II) atoms form equilateral triangles. Within each triangle, a OH atom lies centered on the hexagonal axis; the OH groups reside in an off-center position [59].

Fig. 14.2 Crystal structure of Hydroxyapatite [59].

A fundamental property in the chemistry of apatites, including HA, is that of isomorphous substitutions. Comparison studies of HA, fluorapatite and chlorapatite are of considerable interest in gaining greater insight into the growth of new tissue. Fluoride ions substitute readily for hydroxyl groups in the structure of $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$ because fluorapatite is thermodynamically more stable than HA. The structural–thermochemical model has been used to examine the energetics of the interaction between fluoride, chloride, and hydroxide ions in the Ca channels of HA and the interaction between the Ca channels and groups. The HA structure can be divided into two subsystems: Ca channels containing F^- , Cl^- , or OH^- ions and the calcium phosphate framework [2, 3, 60].

The incorporation of fluoride and chloride ions into the framework is unlikely, while ions may substitute for groups. The two subsystems (Ca channels and framework) are interdependent, and isomorphous substitutions in the Ca channels depend on the energy (strength) of the P–O bonds in the framework. It follows from the above that various substitutions are possible in HA. Certain substituents may occupy, fully or partially, different positions in the HA structure [2, 59].

2.5.6 Dense HA ceramics

Calcium-phosphate-based ceramics can be fabricated by various techniques, depending on the desired microstructure and properties of the material [2]. To produce implants capable of withstanding mechanical loads, it is reasonable to use densely sintered ceramics, which surpass porous ceramics in strength. Dense ceramics can be produced by pressing or slip casting followed by pressureless sintering or hot uniaxial or isostatic pressing. The density of the ceramics thus fabricated approaches theoretical density (3.16 g/cm³ [3]) [2, 61, 62].

The highest possible sintering temperature depends on the sintering atmosphere (partial pressure of water vapor): increasing the ambient humidity stabilizes HA to higher temperatures. At the same time, there is experimental evidence that HA with Ca : P = 1.68 does not decompose at temperatures of up to 1450 °C over a period of 3 h [2].

The key characteristics of dense ceramics are bending strength, tensile strength, and fracture toughness. The bending, compressive, and tensile strength values of HA ceramics lie in the ranges 38–250, 120–150, and 38–300 MPa, respectively [2, 53, 54]. The large scatter is due to the random strength distribution and the effects of residual microporosity, grain size, impurities, etc. With increasing Ca : P ratio, the strength increases, reaches a peak at Ca : P = 1.67, and sharply decreases for Ca : P > 1.67 [2].

Roots of teeth fabricated of dense HA ceramics were studied in vivo and clinically. The bonding between the gum and HA implant was comparable to that ensured by the natural binder. Moreover, good bonding was achieved between the implant and bone. These results are of great importance because inadequate bonding leads to an increased mobility and eventually, loss of teeth. Unfortunately, most of the loaded dental implants were destroyed within a year after implantation because of the low strength of the ceramic [2].

Among the most important applications of dense HA ceramics are hypodermic devices for long-term ambulant intestinal dialysis, monitoring of blood pressure and sugar, and optical examination of internal tissues. Dense HA ceramics exhibit excellent biocompatibility with skin, far exceeding that of silicone rubber, which is widely used for these purposes [53, 2].

2.5.7 Porous HA ceramics

For a number of applications, porous ceramics containing interconnected channel pores are more attractive. Such ceramics can be used as bone graft substitutes, e.g., for the superior articular surface of the tibia, or in drug delivery systems [55, 56]. To ensure blood supply to

contact surfaces and bone ingrowth and fixation [57], the diameter of interconnected pores must be at least 100–135 μm . Also necessary are smaller pores, which favour protein adsorption and adhesion of osteogenic cells. Thus, the pore-size distribution in porous ceramics should be bimodal. Porous ceramics are commonly produced by burning out organic pore formers (polyurethane sponges) or via foaming with the use of hydrogen peroxide [63, 64].

To modify the biological behavior of porous ceramics, the pore surface can be coated with tricalcium phosphate (TCP). To this end, ceramic bodies are impregnated with a dibasic ammonium phosphate solution and then heat-treated at 900 °C [65].

Whereas the compressive strength of porous ceramics is sufficiently high, 2–100 MPa, their bending strength (2–11 MPa) is lower than the necessary level by a factor of 2–3. With increasing porosity, the strength of ceramics decreases sharply. The strength of implants gradually increases in the process of bone ingrowth into the pore network [2]. According to Martin [66], the bending strength of porous implants filled with 50–60% bone tissue is 40–60 MPa.

Porous HA ceramics in the form of blocks and granules find many medical applications. A very important application field for HA granules and porous ceramics is drug delivery. The use of ceramics for solving this problem is a relatively new approach. Although the first studies were carried out as early as 1930, ceramic drug delivery systems were devised only in the 1980s, and the first clinical results were reported in 1998. A major problem with drug delivery systems is to maintain a constant drug concentration in blood over a preset time (slow pharmacokinetics), because periodic peroral or parenteral introduction of drugs may result in drug accumulation to above the permissible concentration. The use of HA ceramics for drug delivery ensures controlled, local drug release over a period of up to one year [67].

2.5.8 Glass-reinforced HA composites

Hench [3] has extensively studied ternary phases of oxides containing some P_2O_5 and evaluated the biocompatibility of the quenched glasses of various compositions.

Glasses within the P_2O_5 –CaO– Na_2O system have been considered as having an enormous potential as biomaterials, because their chemical composition is analogous to the inorganic constituent of the mineral part of bone. Their biocompatibility and bioactivity have also been demonstrated as being adequate, especially as temporary space fillers [68, 69]. Several

attempts [70, 71] have been made in order to reinforce hydroxyapatite and to approximate its mechanical properties to those of bone.

The densification of HA was significantly enhanced by the presence of a liquid phosphate phase chemically related to its composition during its sintering process. Densification occurred by liquid formation, spreading and improving the diffusion mechanism. A strong bonding was developed between HA and the phosphate-based glasses, which acted on the solid HA particles reducing the interfacial energy and eliminating porosity. The presence of a solid HA skeleton (favouring heterogeneous nucleation), the slow cooling rate after sintering, and the tendency of HA to be transformed into tricalcium phosphate at high temperatures, led to the appearance of crystalline α and β tricalcium phosphate (TCP) structures, as was detected using X-ray diffraction. The following general tendency of transformation with increasing sintering temperature was observed: $\text{HA} \rightarrow \beta\text{-TCP} \rightarrow \alpha\text{-TCP}$. The amount of TCP present in the microstructure of the composites depended on the chemical composition of the glass added to hydroxyapatite, as was demonstrated in earlier works [72].

Different calcium phosphates exhibit widely different resorption properties. The resorption property of calcium phosphates depends on Ca/PO_4 ratio, degree of crystallinity and crystal structure. It has been reported the development of resorbable Ca–P–O glass prepared from CaO and P_2O_5 for tooth and bone implant applications. Calcium phosphate glass melts, proven to be biocompatible in the first effort, were cast into carbon molds. In addition, most of the glasses with contents of alkaline oxides can undergo a severe or complete dissolution when in contact with physiological fluids and for this reason they can also be considered as good candidates for bioresorbable implants [3].

3. Experimental procedure

3.1 Characterization of starting material

A commercial hydroxyapatite powder (Budenheim Company, Germany) with a stoichiometric ratio of Ca/P=1.67 was used in this study.

The phosphate glass was prepared with a composition of 32 mol% CaO, 23 mol% Na₂O and 45 mol% P₂O₅. The starting reagents, which were used to prepare the glass, were NaHPO₄, P₂O₅ and CaCO₃. The materials were mixed thoroughly and placed in a platinum crucible, melted at 1000 °C for 1 h, and then poured into a steel plate and allowed to cool. The resulting glass was then ground to a fine powder using an agate grinder. The glass powder was placed in a porcelain mill pot and dry milled for 24 h. After this time, mixtures of HA with 6 wt% and 13 wt% glass had been prepared. These powders were wet milled using methanol for further 24 hours. The resulting slip was then dried at 70 °C and the dry powder was sieved to 75 µm.

The particle size distribution and mean particle size (d_{50}) of HA and glass were determined by the laser diffraction method (Coulter LS230, USA). In order to avoid agglomeration, ultrasonic treatment were used.

The specific surface area of HA powder was determined by the BET method (Areometer; Model Strohlein, Germany). Before the measurement the powder was heated to 200 °C for 30 minutes in order to remove water.

3.2 Slurry preparation and characterization

The slips were prepared by dispersing the HA powder in deionized water, using mechanical stirring. The dispersion behavior of the HA particles was studied as a function of the pH of the slurry and with the addition of two dispersing agents, inorganic (calgon, or sodium hexametaphosphate (Merck Co.,Germany)), and organic (ammonium polyacrylate (NH₄PAA) solution (Dispex A₄₀, Allied Colloids, Bradford,

UK)). The amount of dispersant used here is expressed as a dry weight of the powder basis, equivalent to the wt. /wt. basis of the hydroxyapatite powder.

The HA slips were prepared in deionized water, with optimum amounts of dispersing agents; then milled in plastic jars for 12-24 h, using Al₂O₃ milling media.

3.2.1 Viscosity measurements

Viscosity measurements are widely used to characterize the rheological properties of concentrated suspensions commonly used in ceramic processing. They can be used as a method of analysis of determining the optimum amount of dispersant required for stabilizing a suspension.

The rheological characterization of the slurries was performed with a coaxial-cylinders shear-rate-controlled viscosimeter (Haake VT 550, Germany). Measurements were performed at 25 °C. Flow curves were obtained under continuous shear conditions by changing the rate of shear from 0 to 500 s⁻¹. The shear rate was subsequently reduced to 0 s⁻¹ repeating the cycle three times, in order to determine the steady-state viscosity and flow behaviour.

3.2.2 Measurement of the zeta potential

When an electrical field is applied to a suspension of charged colloidal particles, the particles move with a velocity that is proportional to the applied field strength. The motion is referred to as *electrophoresis*. It can provide valuable information on the sign and magnitude of the surface charge and surface potential. The measured potential is called the ξ -potential and the value of the ξ -potential is a valuable guide to the stability of colloidal suspensions. Modern instrumentation allow the ξ -potential to be measured automatically. For dilute electrolyte solutions, the ξ -potential is given by:

$$\xi = \frac{3\eta u}{2\epsilon\epsilon_0} \quad (16)$$

where η is the viscosity of the liquid, ϵ is the dielectric constant of the liquid, ϵ_0 is the permittivity of free space and u is the electrophoretic mobility.

The zeta potential was determined with a zetasizer (Matec MBS-8000, USA) by measuring the electrophoretic mobility of the particles. Zeta potentials were measured at 3.33 wt.% suspensions with the variation of pH and added dispersant. The pH value of the slurries was adjusted through addition of 1 m KOH and 1 m HCl .

3.3 Layer-wise slurry deposition process

The slurry was processed by a LSD machine device designed by the Clausthal University of Technology [13]. The machine consists of a robot controlled by a PC that is used to deposit ceramic layers by a doctor blade. After spreading, the layer is dried and locally sintered. Then a new layer is deposited and the process is repeated until the ceramic prototype is completed. The machine is equipped with a continuous CO₂ laser ($\lambda = 10.6 \mu\text{m}$) with a beam diameter of $300 \mu\text{m}$, a suitable range for most ceramics to effectively absorb the radiant energy in the infrared range of the energy spectrum.

The LSD process utilizes a CAD file to define the geometry of an object to be produced. The file is sliced into a number of layers that represent cross sections of the object.

Fig. 1.3 LSD device

The layer information is used to control a laser scanner that directs a CO₂ laser to reproduce the layer by selective sintering. Each scanned layer represents a cross section of the sliced CAD model with stereolithography (Stl) format. Finally, an object is created by sequentially sintering the layers with a scanning laser beam.

No support structure is needed as the non-fused powder remains in place to act as a support itself. Excess powder in each layer helps to support the part during the build. Fig. 1.3 shows LSD device.

3.4 Characterization of the LSD HA and glass-reinforced HA composite parts

Layers has been laser sintered and also green bodies were air-sintered in the temperature range of 1000-1300 °C for 2-3 h, cooling inside an SiC furnace. Sintering tests were carried out in all cases with the heating rate was 10 °C/min. The sintered samples, polished successively with 400 and 600 grit SiC emery and 2 μ Al₂O₃, were etched with 0.1M acetic acid for 2 min and HCl for 15 second. Also laser sintered samples were thermal etched at 1300 °C for 0.5 h.

3.4.1 SEM investigation

The microstructures of the sintered HA parts were examined using scanning electron microscopy (SEM; Model Camscan CS4, UK). Porosity of the sintered samples was examined by SEM. A gold layer was sputter coated onto the samples prior to SEM observation.

3.4.2 XRD analysis

Phase compositions of samples were determined by X-ray diffraction (XRD; Model PW 1710, Philips, The Netherlands) using CuK_α radiation at 40 kV and 30 mA. Quantitative phase analysis was performed by using from pure HA, α-TCP, β -TCP and C₄P as reference materials. Philips APD analysis software has been used for calculating of the samples phases values to compare with reference materials. It has been evaluted by calculating the area of the most intense peak of samples. All the

peaks of the ceramic were compared with JCPDS powder diffraction data card No. 9-432 and were assigned to HA.

All peak area calculations were performed using curve fitting and the error was estimated to be around $\pm 2\%$ of the mean value.

3.4.3 DTA analysis

Thermal behavior of HA powder was examined by simultaneous thermo analysis (STA; Model 429, Netzsch, Germany) at a heating rate of $10\text{ }^{\circ}\text{C}/\text{min}$ up to $1550\text{ }^{\circ}\text{C}$ in air atmosphere.

3.4.4 FTIR analysis

Fourier transform infrared spectroscopy (FTIR) (Bruker-vector 33, USA) was conducted since it allows analyzing materials characteristics that can not be differentiated by means of X-ray diffraction. The powders and the crushed laser sintered samples were mixed with dried potassium bromide (KBr) powders at a concentration of 1 wt. % and subsequently compressed to produce a transparent tablet. The infrared spectrum with a resolution of 8 cm^{-1} and the scan number of 4 was adopted with a spectral region from 400 to 4000 cm^{-1} . FTIR analysis was applied to examine the contents of OH^- groups in the samples types.

3.4.5 Porosimetry measurement

Mercury porosimetry measurements were carried out on a micromeritics poresizer (Strumentazione, Carlo Erba 200, Italy)) to determine the pore size distribution. This method requires sample volumes in the range 2 cm^3 .

The obtained porosities were gathered in 5 porosimetric intervals of pore radius. The values coming from the porosimeter are taking into account the porosity of the sample (in practice the overall volume of mercury threaded into the ceramic body referred to the volume of the sample), was calculated the absolute porosity (AP%) listed in another column; a third column reports the volumetric porosity (V_p) as the amount of porosity referred to the sample volume. The pore-size distribution follows the relation:

$$d = - \frac{4\gamma \cos \theta}{P} \quad (17)$$

where d is the pore diameter, γ is the surface tension, θ is the contact angle, and P is the mercury pressure. The pore diameter was calculated from the pressure applied to the ceramic bulk, and the total open porosity was calculated from the mercury intrusion volume.

3.4.6 Density measurement

The Archimedes water immersion technique was found to be the best in measuring density and open porosity. Specimen density was measured on each sintered specimen using the Archimedes principle. The measurements were carried out in distilled water. These were then compared with the theoretical densities (density of 3.16 g/cm³ for HA).

Also, the HA-glass layer-wise sintered bulk density was measured by Archimedes method and relative values were calculated assuming that the theoretical density of glass powder has been determined with picnometry method to be 2.60 g/cm³. From these, the overall theoretical density of the sample could be determined by:

$$(P_{\text{HA}} \cdot \rho_{\text{HA}}) + (P_{\text{glass}} \cdot \rho_{\text{glass}}) = \text{Overall theoretical density} \quad (18)$$

which, P and ρ are weight % and density of material, respectively.

4. Results and discussion

This research was divided in two parts: (1) investigation on rheological properties of the hydroxyapatite slurries that play an important role in facilitating the layering operation (2) studying the compositional and structural changes of the samples of HA and HA glass-reinforced composite layer-wise slurry deposited after laser treatment and comparing with sintered layers by conventional sintering. One ultimate aim in this process is to fabricate the three-dimensional parts directly from ceramic materials without using any intermediate binders.

4.1 Dispersion of hydroxyapatite powder in aqueous media

4.1.1 Particle/ floc size distribution

The particle/floc size distribution of HA powder showed that the HA powders with a median diameter (d_{50}) of 4.89 and 4.58 μm for the as-received and the calcined powders at 1000 °C, respectively, were highly agglomerated when dispersed in deionized water (Fig. 1.4). On the contrary, the particles were well dispersed in the presence of NH_4PAA and calgon as dispersant agents, as shown by the shift in the particle-size distribution curves to finer ranges with minimum values for particle sizes (dispersant of NH_4PAA : $d_{10}=0.476 \mu\text{m}$, $d_{50} = 1.962 \mu\text{m}$, $d_{90} = 6.747 \mu\text{m}$; dispersant of calgon : $d_{10} = 0.557 \mu\text{m}$, $d_{50} = 2.227 \mu\text{m}$, $d_{90} = 4.924 \mu\text{m}$).

4.1.2 The effect of dispersants on aqueous dispersibility of the HA powder

The effect of dispersant on the dispersibility of the commercial hydroxyapatite powder was investigated by measuring the viscosity and the zeta potential of the suspension. Fig. 2.4 shows the zeta potential vs. pH of HA powder with and without dispersants in water. When the pH value is below and above the isoelectrical point, the charge on the surface of HA particles is positive and negative, respectively.

In general, the dispersion of ceramic powders in suspensions can be improved when the absolute value of the zeta potential is increased after an addition of dispersant. In the alkaline region the zeta potential is slightly improved in the presence of a

dispersant as expected, since the charge of the polyelectrolyte is added to the particles surface charge.

Fig. 1.4 Particle-size distribution of HA as-received and calcined powders in deionized water, with and without dispersant

Fig. 2.4 Zeta potential vs. pH of HA suspensions with and without dispersants.

It can be seen that after addition of calgon and NH_4PAA the isoelectrical point of HA powder shifted from pH 10.2 to about pH 9.6 and 9.5, respectively. The results in Fig. 2.4 indicate that NH_4PAA is a more effective dispersant for HA powder than calgon because of the higher absolute value of the zeta potential, with increased charge density on the surface of the powder particles and increased repulsion among particles.

NH_4PAA is an anionic polyelectrolyte and can dissolve in aqueous solution, producing negatively charged carboxyl groups [shown in Eq(1.4)], which are very easily adsorbed on the positively charged HA surface. Consequently the powder is negatively charged and this results in a shift of the isoelectrical point to a lower value. The dissociation of NH_4PAA in water can be described as follows [73]:

Polyacrylates have proved to be effective dispersing agents for both clay- and nonclay-based ceramics [74, 75], through an electrosteric mechanism of dispersing action. Similarly, various sodium polyphosphates have been used as effective deflocculating agents for many clay- and oxide-based ceramic systems [76]. The polyphosphates may act as either cationic (Na^+) or anionic (polyphosphate groups) dispersants, depending on the charge of the particle surface. Because of their long chain structure, polyphosphates—e.g., sodium hexametaphosphate—provide a steric hindrance effect, along with the electrostatic dispersion effect [77].

On dispersion into aqueous media, the HA particles could have on their surfaces various ions such as Ca^{2+} , CaOH^+ , PO_4^{3-} , HPO_4^{2-} , H_2PO_4^- , and $\text{CaH}_2\text{PO}_4^+$, depending on the dissolution and the hydrolytic reactions in solution, bringing into play a set of complex flocculating/deflocculating mechanisms. However, because HA slips could be dispersed and stabilized by the anionic polyelectrolytes, as well as by a polyphosphate, it can be concluded that the surface of HA is positively charged and the positive charge attributed to the specific adsorption of Ca^{2+} ions or to preferential dissolution of phosphate ions from the apatite surface [78, 79].

At the isoelectrical point the number of the positive charge sites presented by adsorbed H^+ ions is equal to the negative charge site of adsorption of OH^- ions, so the

net charge equals zero, and the particles in the suspension can be easily agglomerated. Under acidic and basic conditions when more HCl or NaOH are introduced, the increased ionic strength in the suspension increases the thickness of the double electric layer, resulting in an increase of the absolute value of zeta potential of the powder.

The size of HA agglomerates versus pH of aqueous suspensions is shown in Fig. 3.4. The agglomerate size is about 4 - 4.3 μm under the condition of $\text{pH} < 8$ or $\text{pH} > 11$ for the calcined HA powder. However, the agglomerate size approaches 10.8 μm at near pH 10.2, which shows an agglomeration state. Also, it can be seen that a relatively uniform size of about 1.65 μm in pH 12 and up to 3.27 was achieved in the wide pH range of 4 to 12 in HA powder with addition of NH_4PAA .

Fig. 3.4 Agglomerate size of the calcined HA powder without and with NH_4PAA at different pH values.

4.1.3 The effects of powder pre-treatments on powder characteristics and surface charge of HA suspensions

Fig. 4.4 shows the specific surface area as a function of calcination temperature. A great decrease in the specific surface area has taken place for the powder calcined at

temperature between 700 and 1000 °C. The surface area decreased from 65.2 m²/g, for the as-received powder to 4.6 m²/g for the powder calcined at 1000 °C.

Fig. 4.4 Influence of the heat treatment on specific surface area (BET) of HA powders.

The particle size distributions reported in Fig. 5.4 are evidence that as-received powder is characterized by larger agglomerates formed primary particles in comparison with the pre-treatments powders at 900 and 1000 °C in the presence of 1 wt% NH₄PAA as the dispersing agent. It can be also observed that the as-received powder seems much more difficult to dispersing compared to the calcined-powder. This confirms the increased difficulties of dispersing the as-received powders. The calcination of HA powder prepared at 1000 °C was pure single phase HA, as shown by the X-ray diffraction presented in Fig. 6.4. The reflections of the XRD spectrum very well agree with as-received HA powder.

FTIR spectra (Figs. 7.4 (a, b)) provide evidence that the presence of a higher amount of HPO₄²⁻ in powders as-received in comparison with the powder calcined at 1000 °C. On the contrary, the O-H stretch band around 3450 cm⁻¹ is more accentuated for the powder calcined at 1000 °C.

The study of the behavior of HA powder in aqueous media gives some information about its actual chemical reactivity in the biological environment, because it is mainly

based on aqueous salt solutions. For this purpose the solubility of HA in water has been extensively studied [80].

Fig. 5.4 Particle-size distribution of HA powders as-received and calcined at 900 and 1000 °C in the presence of 1 wt% of dispersant NH_4PAA .

Fig. 6.4 XRD pattern of HA powders (I) as-received (II) calcined at 1000 °C

Fig. 7.4 FTIR spectra of powders (a) as-received (b) calcined at 1000 $^\circ\text{C}$. The main absorption bands are indicated.

The stoichiometric dissolution of HA is very low ($\text{p}K_{\text{sp}} = 115$) [81], but nonstoichiometric dissolution due to the formation of surface complexes was

demonstrated to occur and to cause phenomena of meta-stable equilibrium solubility [82].

In particular, a solid surface complex $\text{Ca}_2(\text{HPO}_4)(\text{OH})_2$, formed by HA hydrolysis mechanism, controls the solubility equilibria, according to the following equations [80, 83]:

The resulting non-stoichiometric Ca/P ratio in solution (1:1 for Eq. (20) or 2:1 for Eq. (21)) depends on which dissolution reaction prevails. If HA is prepared in water, the surface is, presumably, just covered with surface complex $\text{Ca}_2(\text{HPO}_4)(\text{OH})_2$ and subjected either to the equilibrium shown in Eq. (21) or to adsorption phenomena of ionic species present in solution [84].

Generally speaking, the surface charge of apatite solids is the result of pH and preferential dissolution or adsorption of calcium and phosphate ions, since H^+ , OH^- , and lattice ions are the potential determining ions. The formation of surface complexes between potential-determining ions further complicates the estimation of ion activity product and surface potential [85].

Fig. 8.4 reports the influence of different pre-treatments on zeta potential of HA powder. It can be seen that the pH of the isoelectrical point (10.8) of the as-received powder is located at about pH 9.5 for the calcined powder at 1000 °C. This pre-treatment is believed to be the one that less interferes with the surface charge properties. Conversely, calcinations accentuated the surface acidity of HA powder shifting the pH_{iep} from 10.8 to 9.5. The zeta-potential curves for the as-received powder and calcined powders are almost coincident, especially in the acidic side of pH range. For pH values higher than 9.5, the zeta potential of the calcined powder appears more negative compared to the as-received powder.

Therefore calcinations would be responsible for an increase of the surface groups, enhancing a more negative potential and consequently, the repulsion between particles. The highest specific surface area of as-received powder, reflecting in the formation of the highest quantity of the $\text{Ca}_2(\text{HPO}_4)(\text{OH})_2$ complex, provides a shift of the natural pH toward the most basic value.

Fig. 8.4 Influence of pre-treatment on zeta-potential of HA powders a) as-received; b) calcined at 800 °C; c) calcined at 900 °C; d) calcined at 1000 °C (deagglomeration in water with presence of 1 wt.% NH_4PAA).

The establishment of a cationic specific adsorption determines a shift of the pH_{iep} of the as-received powder toward basic pH. This strong shift (about pH_{iep} of 10.8) can be due to the higher content of Ca^{2+} ions, leached from the surface complex. In the basic side of the titration curve the absolute value of the zeta-potential seems to be related to the Ca^{2+} concentration in the solution. In fact, above the pH_{iep} , the absolute value of the zeta potential is smaller, with a higher content of Ca^{2+} in solution (the zeta potential at pH 12.2 is -29, -24, -20 and -14 mV for calcined powders in 1000, 900, 800 °C and as-received powder respectively). Above pH_{iep} , the particles become negatively charged and start to repel the dissociation of the groups of the polyelectrolyte chain.

The surface chemistry of powders dispersed in aqueous media can be modified in order to produce repulsive inter-particle forces that promote dispersion. Polyacrylates have proved to be effective dispersing agents for both clay- and nonclay-based ceramics, through an electrosteric mechanism of dispersing action. Their combination

is important especially in the case of high solids concentration where the average inter-particle distance is short [86, 87].

The calcination at 1000 °C resulted in a significant increase of the absolute value of zeta-potential. Fig. 9.4 shows optimum values of dispersant for the 66 wt% slurry in different calcination temperatures. At low amounts of dispersant, the electric double layer is not enough to achieve stabilization and prevails the attraction between particles but at optimum value of dispersant, slurry achieves stability and the lowest viscosity. When a higher amount of dispersant is added, the electric double layer is compressed by too high electrolyte concentration and the electrostatic repulsion is less effective and therefore, the viscosity increases. Besides, an excess of non-adsorbed polyelectrolyte in solution could provide a viscosity increase. It is observed that the lowest dispersant values could be obtained when powder is calcined at 1000 °C. The minimum viscosity is reached in concentrations of 0.35 wt% NH₄PAA when the powder is calcined at 1000 °C. Whereas, for HA calcined at 900 °C the best concentration was 2.2 wt% NH₄PAA. A great decrease of viscosity is observed when the HA calcined powder at 1000 °C were used, being those slurries prepared with very fluid with viscosity of 0.24 Pa s at 100 s⁻¹ for 66 wt% solid.

In order to study the content of admissible solid, slurries containing 66 wt% of the as-received HA powder were prepared using a concentration of 3.5 wt% NH₄PAA. The slurries had a paste-like consistency. In the case of the as-received powders, the starting solid loading could not exceed 41wt% due to more accentuated viscous characteristic of these suspensions.

The slurries made of powder calcined at 1000 °C were always more fluid than those made of powder calcined at 900 °C for the all concentrations of the studied dispersant. Part of the liquid in slurry is immobilised inside the pores of agglomerates, therefore the effective volume of liquid would be higher in powder with lower porosity. Porosity decrease significantly as the calcination temperature increases. Therefore, the viscosity of powder calcined at 1000 °C would be lower.

Therefore, in addition to the chemical composition and surface area of the powder, another factor influencing slurry fluidity should be presented. Calcination affects on reduction of the dispersant dramatically. This difference is significant and reveals that

the as-received powders are more difficult to disperse than the powder-treated ones, as expected from the above discussion. The rheological behavior of the as-received powders suspensions would be mainly determined by the surface characteristics of the component.

Fig. 9.4 Optimum values of dispersant for the 66 wt% HA slurry versus calcination temperature.

4.1.4. Influence of deagglomeration time on dispersibility and rheology

Fig. 10.4 shows the particle-size distribution for the HA powder calcined at 1000 °C with 1 wt% NH_4PAA dispersant in conditions of without milling and different times of ball milling. Ball-milling the calcined suspension for 24 h has caused a reduction in the number of agglomerates and a consequent increase in the number of the average sized particles. The effect of deagglomeration time on the rheological characteristics of the 66 wt% slurries prepared from the 1000 °C-calcined powder are reported in Fig. 11.4. These slips have a shear-thinning behavior for a lower range of shear rates (up to 30 s^{-1}) and shear thickening (dilatant) at higher shear rates in conditions of before milling and after ball milling for 6h.

Fig. 10.4 Particle-size distribution of HA powders calcined at 1000 °C as a function of the milling time (with 1 wt% NH_4PAA)

Fig. 11.4 Viscosity vs. shear rate for the 66 wt% HA slurry as a function of the milling time.

Fig. 12.4 pH of the 66 wt% slurry as a function of the milling time.

On the contrary, after ball milling for 12 and 24 h, Fig. 11.4 shows relatively lower viscosity with shear-thinning for a lower range of shear rates (up to 30 s^{-1}) and near-newtonian behavior at higher shear rates. The shear-thinning characteristic decreases with increasing deagglomeration time.

The results presented above show that the deagglomeration is promoted by ball milling and by increasing duration of the contact time between solid and liquid phases (at least up to 24h). However, this is a long duration process and hydrolysis reaction of the HA powder in water may increase the amount of OH^- in the powder surface. Fig. 12.4 proves this idea. This figure shows increasing the pH with increasing the ball milling time. These effects improve the dispersing ability of the HA-based composites and enables the use of an incremental process to obtain highly concentrated (up to 75 wt %) aqueous the HA-based suspensions.

Fig. 13.4 shows the viscosity vs. the shear rate for the HA slurries of the 1000 °C-calcined powder with 0.75 wt% of NH_4PAA in an incremental process (3 wt%) up to 75 wt% and 24h ball milling time. The slips were ball-milled for at least 6h before the incremental amounts of 3 wt% solids have been added, up to final concentrations of 75 wt%.

Fig.13.4 Viscosity vs. shear rate for HA slurries with the 1000 °C calcined powder (with 0.75 wt% NH_4PAA).

Fig. 14.4 Viscosity vs. dispersant concentration of NH_4PAA (shear rate of 100 (1/s), 60-75 wt. % HA slurries)

The shear-thinning characteristic enhances by increasing the solids loading and deagglomeration process continues by increasing the solids loading, although at the lower rate as was expected, since the suspensions become more viscous. The viscosity of the slurries with solids loading of 66 and 69 wt% are very low and the suspensions exhibit Newtonian behaviours. The viscosity of the slurries with 72 and 75 wt% are higher but, they are still fluid and easy to deposit by doctor blade and they show a shear thinning behaviour at low shear rate (100 and 200 s⁻¹ respectively), whereas at higher shear rates, slight shear-thickening (dilatant) behaviour has been observed.

This initial shear thinning, followed by a shear-thickening phenomenon, is a well-known characteristic of colloidally stable suspensions at higher solids loadings. The initial shear thinning could be attributed to the increased tendency of flocculation, and the dilatancy at higher shear rates can be ascribed by shear-induced flocculation or transition from an ordered to a disordered structure as the interparticulate distances decrease with increasing solid loadings [19, 88].

Fig. 14.4 shows correlation between viscosity and the NH₄PAA content for the slurries with 60 to 75 wt% of solid loadings. The viscosity data are recorded at a constant shear rate of 100 s⁻¹. Initially, the viscosity decreases remarkably with increasing the dispersant content and reaches to a minimum value at 0.2, 0.35, 0.6 and 0.75 wt% of NH₄PAA content for the slurries with 60, 66, 70 and 75 wt% of solid loadings, respectively.

The results of slurry-optimization experiments reveal that a well-dispersed HA slurry could be prepared in deionized water up to a 75wt% solids loading, using dispersant of NH₄PAA, in optimum amount. The slip viscosity could be further decreased by breaking down the soft agglomerates through milling of the slip in polyethylene bottles with alumina milling media for various times, as indicated by the flow curves of viscosity versus shear rate for HA slips.

4.2 Composition of HA slips for the LSD process

By the LSD process is produced the three-dimensional components in a layer-by-layer build sequence that involves computer-controlled deposition of a concentrated

colloidal suspension. Current challenges to this approach involve controlling macroscopic shape evolution during deposition to avoid unwanted deformation.

The lower content of solid (<66 wt%) in the slurries has caused cracking after drying due to excessive shrinkage and the higher content of solid (>75wt%) in the slurry has too high viscosity for deposition.

A stable suspension has been achieved with viscosity of 0.36 Pa s at shear rate of 100 s⁻¹ for 75 wt% solid loading with 0.75 wt% NH₄PAA as dispersant, which is suitable to deposit by doctor blade. The suspensions generally exhibited a transition from shear thinning to shear thickening flow as shear rate exceeded a certain critical level. But, at the applied speed of pump (1300-1600 rpm/min) the slurries have a shear thinning behavior. During the process, no sedimentation occurred for several hours.

In order to facilitation of the layering operation, 0.02 wt% surfactant (sodium dodecyl sulfate, Fluka Co., Germany) and defoamer (surfynol DF-58, Air products Co., Holand) has been used. These materials are added to slurry and mixed for 10 minutes.

A well dispersed and highly stable slurry with low viscosity and high solid content to control the shrinkage are the required characteristics to obtain the defect free green layers. Slurry preparation usually involves particle deflocculation and dispersion in a solvent using dispersants and slurry homogenization with mixing and ball milling, which strongly influence the green layers characteristics.

4.3 The drying behaviour of the HA layers at the LSD process

In the LSD process, shaping and drying processes occur simultaneously. During drying, the fluid is removed via evaporative processes. This technique yields flat, thin ceramic sheets with thickness as such as 100 µm.

After minimal drying, the next deposited suspension undergoes a liquid to solid transition.

The layer thickness at the LSD process depends on

- a. Viscosity of the slurry
- b. Speed of the doctor blade moving
- c. Doctor-blade gap setting
- d. Reservoir depth behind the doctor blade (corresponding to pump speed)

In the most cases, the speed of the doctor blade moving and the pump speed are between 100-120 mm/s and 1300-1600 rpm/min, respectively.

The problems in layering and drying behaviour are the cracks during drying that has been solved by higher solid loading and lower viscosity (more milling) of the optimized slurries (according of Eq (14), see; chapter 2).

Also, in practice, high dispersant content can lead to problems during drying. Cracks have been observed at higher additive concentration (more of 1 wt %). This observation was attributed to bridging effects resulted from salt precipitation in the final stage of drying. The migration of such species to the external surface of these layers during drying was also evident which leading to severe microstructural nonuniformity.

However, the drying temperature has been adjusted at 90 °C by heating of the ceramic substrate. Slower drying (lower temperature and /or air flow) have been helped to avoid the cracks formation (according of Eq (14)).

Drying is a critical step in colloidal processing of ceramic films and bulk forms. It is a multistage process that involves capillary-driven fluid flow, viscous deformation of the body (or film), evaporation, and diffusion. Removal of the liquid vehicle required for colloidal processing often leads to problems with dimensional control, segregation, and cracking [89, 90].

A minimum solid loading of 66 wt% showed to be effective in avoiding cracks formation and uneven shrinkage and forth shape maintenance. In these cases, the solid loadings in slurries are typically limited to about 75 wt%. Ideally, the slurries should have the highest solids loading with the lowest viscosity. High solids loading help to reduce the shrinkage and related cracking possibilities during the sintering of green body, while low viscosity reduces defects as such as cracks and delamination in deposited layers.

4.4 Comparative study of the LSD green layers

As expected, the films produced from dispersed suspensions yielded higher packing densities than those produced from aggregated suspensions. As described, one must tailor interparticle forces, suspension rheology, consolidation, and drying behavior to achieve the optimal microstructure for a given application. Problems such as large shrinkage during firing and green body cracking are likely to appear.

The slurry was deposited to a thin tape on ceramic substrate with doctor blade initial gap setting of $100\text{ }\mu\text{m}$. This gap is kept constant in all the experiments. After 2 minutes of drying, the next layer is deposited. The fabricated green layers were used for comparative studies based on visual inspection, green density. The green density of the layers was determined using a geometrical technique. Three samples ($2\text{ cm}\times 2\text{ cm}$) are taken from different locations of green layers. The thickness of the sample were measured at different locations on the samples by using a micrometer with the accuracy of 0.001 mm and an average was taken for the calculation of the volume. By knowing the mass and volume, the green density was calculated. High green density and solid content indicate that the powder is filled in the green tape uniformly. By using the highest solid loading, the HA suspension is attained crack-free parts, produced green bodies having densities at the range of 56.6% of theoretical ($3.16\text{ g}\cdot\text{cm}^{-3}$). Fig. 15.4 shows the green density of HA layers as a function of the solid loading of the slurries.

Fig. 15.4 Geen density of HA layers as a function of solid loading of slurries.

4.5 Laser sintering of the HA layers

4.5.1 The effect of laser parameters on microstructure

The slurries with solid loadings of 66 and 75 wt% showed to be effective in avoiding cracks formation and uneven shrinkage. A continuous CO₂ laser beam controlled by a PC was used to sinter each layer that was deposited by doctor blade casting.

The rate of energy absorbed by the surface area depends on the intensity of the laser irradiation, the period of a single exposure, the number of total exposures, and the time between each exposure. According to the optical properties of the powder, a portion of irradiation is absorbed and the reminder is reflected. The absorbed energy is either conducted into the powder bed or transferred to the surroundings through radiation or convection at the surface [91].

Nelson [91, 92] has shown that one of the key processing parameters in the selective laser sintering (SLS) process is the absorbed energy density (AED)

$$AED = \left(\frac{P}{\pi\omega^2} \right) \left(\frac{2\omega}{BS} \right) \left(\frac{2\omega}{SS} \right) \quad (22)$$

ω is the effective laser beam radius, P is the laser power, BS is the beam speed, and SS is the scan spacing. The first term on the right hand side of Eq.(22) is the power density of the laser beam, the second indicates the time that a circle of radius is under the laser beam during one single pulse, and the third estimates the number of pulses received by the same circle. Practically, the distance between two adjacent scan lines, SS, is less than the laser beam diameter to permit each point of the surface to receive several pulses [92, 93].

AED from Eq.(9.4) can be expressed in (cal/cm²) as:

$$AED = \frac{23.9P}{(BS)(SS)} \quad (23)$$

where P is the laser power in watt, BS is the laser speed in m/s, and SS is the scan vector spacing in μm .

Fig. 16.4 Variation in the penetration depth with absorbed energy density.

The penetration depth (D_p) increases by increasing the laser power (P) and by the decreasing the beam speed (BS). Fig. 16.4 shows the penetration depth vs. variation of AED. In the LSD process the largest slice thickness is limited by the penetration depth. Fig. 17.4 shows the morphology of a cross section of the samples sintered at different conditions.

The slice thickness is an important factor that influences the period of the whole process and surface roughness. A reduced layer thickness causes a decrease in surface roughness and an increase in accuracy of the shape since the step effect is minimized. But it takes more time to build up a component than large slice thickness does. Thus, density decreases and the surface finishing improves. A reduction of the layer thickness allows for a faster scan velocity, because the necessary sintering depth is also reduced to ensure a fusion to the previous layer is reduced, too. In our experiments, the smallest layer is 100 μm high.

After laser sintering of each layer, the powder is cooled by convection and radiation heat exchange to its surface and by conduction into neighbour layers. The laser beam speed and the scanned vector length may determine the cooling period. The scan spacing should not be too large, because the cross section of a layer may not be

completely sintered. However, this is related to the laser beam diameter and the rate of applied energy density, but for effective sintering the scan spacing should not exceed the beam diameter [92, 93].

Fig. 17.4 Scanning electron micrographs of layer cross-sections showing the penetration depth of laser sintered HA at various conditions: (a) P: 18 W, BS: 30 mm/s, AED: 143.4 cal/cm^2 , $D_p: 100 \pm 3 \text{ μm}$ (b) P: 18 W, BS: 10 mm/s, AED: 430.2 cal/cm^2 , $D_p: 130 \pm 4 \text{ μm}$ (c) P: 24 W, BS: 30 mm/s, AED: 191.2 cal/cm^2 , $D_p: 110 \pm 3 \text{ μm}$ (d) P: 24 W, BS: 60 mm/s, AED: 95.6 cal/cm^2 , $D_p: 80 \pm 2 \text{ μm}$. Samples of A, B, D consist of 1 sintered layer and sample C consists of 9 sintered layers.

In practice, in laser sintering of HA samples, the distortion is more than shrinkage, especially for direct laser sintering in which high temperature is applied to sinter high melting-point materials like HA. The shrinkage affects not only the final dimensions of parts, but also result in distortion and warpage. In general, the distortion and warpage can be eliminated by optimizing the process parameters like laser power, scanning speed and scanning spacing etc, for the direct laser sintering process. Therefore, here, the optimized parameters have been discussed.

In these experiments, the thickness of the slurry layer and the scan spacing (SS) were kept constant at 100 μm , the beam speed and the laser power were varied in the range of 10 - 60 mm/s and 18 - 24 W, respectively. The absorbed energy density (AED) was varied in the range of 95.6 – 430.2 cal/cm^2 as estimated by Eq. (23).

The microstructures analyzed by SEM are shown in Fig. 18.4. The sintered samples have a pore size of 40 -80 μm when the energy density, AED, varies between 95.6-191.2 cal/cm^2 . A higher amount of energy increases the temperature locally at the powder bed, which to result in a large amount of liquid phase formation. An increase in laser power leads to an increase in the density of the specimen, since more energy is delivered into the powder and larger melt pools fill up the porous structures of previous layers. As the laser power was increased, a transition from sintering mode to the remelting of sub-layers was observed. However, surface roughness also increases because the molten particles tend to form larger spherical structures. Increasing the scan speed has the opposite effect due to higher velocity of the laser, less energy is delivered into the powder bed and less material is melted and less time is available for the formation of agglomerations.

The maximum density achieved was approx. 63-68 % of theoretical density. The morphology of the obtained the layers is depending on the absorbed energy density. At high energy density, the porosity is finely dispersed.

Fig. 19.4 shows the pore size distribution of the green layers and laser sintered samples at different cases of absorbed energy density.

4.5.2 The effect of solid loading on microstructure

SEM analysis of the porous materials shows that the morphology and distribution of the micropores may be related to the rheological properties of the suspensions.

In Fig. 20.4, the laser sintered porous bodies obtained with 75 wt % slurry with green density of 56.6 % of theoretical density are shown. The size of the pores is approximately between 40 and 60 μm . The actual pore size of the porous ceramics is estimated from scanning electron micrographs.

Moreover, microstructure of the laser sintered bodies obtained with 66 wt % slurry is characterized (Fig 18.4 a, b) that have green density of 53.1 %. In comparing these cases show higher solid loading (75 wt%) of slurry lead to the reduction of the final pore sizes at samples in respect to slurry with 66 wt% solid loading. Fig. 21.4 compares the distribution of pores size for the laser sintered samples of prepared with slurries of 66 and 75 wt% solid loadings. The data reported in Figs. 20.4, 21.4 signify that the pore size distribution is well correlated with the solid content of slurries.

4.5.2 The effect of laser parameters on phase composition

The results of the simultaneous thermal analysis (STA) of HA powder used in this study are shown in Fig. 22.4. The TG curve indicates a weight loss of the powder due to dehydration reactions. An exothermic peak occurs at about 1200 °C relating to OH⁻ groups which are lost gradually. An endothermic peak occurs at about 1390 °C and it may refer to the phase transformation from HA to TCP or even C₄P. The thermal decomposition of pure apatite has been reported to occur at 1380 and 1475 °C and a liquid forms at 1570 °C [according to the phase diagram (Fig. 13.2)]. But thermodynamics tells us how a material is supposed to behave if sufficient time is allowed for the system to reach equilibrium at any given temperature and pressure. Since, in most cases, this requires long-range diffusion of atomic species through solid and/or liquid phases, equilibrium is rarely achieved in practice.

Fig. 23.4 compares the phase composition of a layer before and after laser sintering. It reveals the presence of HA and α -TCP phases after laser sintering.

A possible presence of glass phase is demonstrated in FTIR curves of Fig. 24.4. The entire disappearance of the peak labeled at 3570 cm⁻¹, which is assigned to stretching mode of OH⁻, together with the broad peak at around 1000 cm⁻¹ suggests the existence of amorphous calcium phosphate (ACP) in this layer [94].

Fig. 22.4 Thermal analysis of the HA powder (at a heating rate of 10 °C/min, in air).

Fig. 23.4 XRD plots showing one HA layer a) before laser sintering; b) after laser sintering: P: 24 W, BS: 30 mm/s, AED: 191.2 cal/cm²; c) after laser sintering: P: 18W, BS: 10 mm/s, AED: 430.2 cal/cm².

Fig. 24.4 FTIR spectra of (a) HA powder and (b) the laser sintered layer (P: 18W, BS: 10 mm/s, AED: 430.2 cal/cm²).

It has been shown that ACP was beneficial for accelerated fixation and remodeling of the prosthesis in the calcium phosphate coatings [95].

As the energy density level of the laser is increased, the amount of other involved chemical compounds increases (Fig. 25.4).

Fig. 25.4. XRD plots of the laser sintered HA layers a) P: 20 W, BS: 10 mm/s, AED: 478 cal/cm²; b) P: 24W, BS: 10 mm/s, AED: 573.6 cal/cm².

Table. 1.4 Quantitative phase analysis results of laser sintered HA samples.

Samples No.	Conditions of sintering			Phases composition (%) ± 2			
	P(W)	BS(mm/s)	AED(cal/cm ²)	HAP	α -TCP	C ₄ P	amorphous
1	24	60	95.6	91	5	-	4
2	24	30	191.2	74	16	-	10
3	20	10	478	68	14	10	8
4	24	10	573.6	46	21	20	13

The samples produced at various power levels show that decomposition takes place at higher temperatures. At lower power levels, tricalcium phosphate (TCP) will appear but more severe heating will also produce tetracalcium phosphate (C₄P) and TCP (Fig. 25.4 a, b). The former two phases are the equilibrium phases at high temperature and low partial water pressure. Also, crystalline peaks become less sharp and broaden after laser sintering. This indicates that melted portions of HA particles solidify into an amorphous phase after laser sintering.

Table. 1.4 shows the results of quantitative phase analysis of the laser sintered HA samples.

Cihlar et al [96] have studied the mechanism and kinetics of thermal decomposition of injection moulded HA ceramics over the temperature range of 1473-1758 K. They showed that between 1473 and 1758 K, hydroxyapatite is decomposed while releasing water and producing tricalcium phosphate. The first water was expelled at above 1173 K and the dewatering proceeded even at 1758 K (a conversion degree of about 0.9 being attained at the latter temperature). The onset of hydroxyapatite decomposition yielding TCP was detected at 1623 K. Diffractions of tetracalcium phosphate (C₄P) appeared about 1773 K. On the basis of the obtained results, the following scheme of thermal decomposition of HA ceramics for the temperature interval of 1173 to 1758 K was proposed:

1173 -1623 K

1623 -1758 K

C₄P started to form at temperatures above 1750 K according to the equation

The first equation of the scheme, describing conversion of HA to oxyapatite (HOA) and liberation of water, was examined thermogravimetrically. No significant differences were established between the diffraction spectra of HA and HOA. The second equation of the scheme, describing the thermal decomposition of HOA to α -TCP and CaO, is based on the results of diffraction analysis. Diffraction lines of two crystalline phases, HOA and α -TCP, were found in the spectra within the temperature range of 1623 to 1758 K. Whereas, numerous authors [97, 98, 99] stated that the onset of decomposition of HA to TCP and C₄P occurred at the same temperature, in their case and under all conditions the formation of C₄P was confirmed to take place at temperatures higher at least 130 K than the formation of TCP (1623 vs. >1758 K). The minimum temperature of TCP established 1623 K by the other authors [97, 98, 99] that does not likewise agree exactly with the literary data. It has been assumed that the differences are most likely due to different arrangements of their experiments (kinetic study of decomposition of HA ceramics), to the purity of reagents and to water vapor content in the furnace atmosphere. The mechanism of thermal decomposition of HA ceramics involves four processes: sintering, removal of water, decomposition of HA to TCP, and formation of C₄P [96]. The sintering caused the HA ceramics to shrink by at least 30 vol%. On neglecting the fact that thermal exposure changes the composition of the HA ceramics, the 30% shrinkage would correspond to a relative density of about 0.93. During sintering, the “open” porous structure was transformed into closed pores. The time required for maximum shrinkage and closing of pores in the HA ceramics was decreasing with increasing temperature. An equilibrium is established between HOA and H₂O (reaction 12.4) and the decomposition of HOA stopped. At higher temperature (≥ 1673 K), HOA started to decompose to TCP. The defects in the HOA lattice and its transformation to the TCP lattice, as well as the surfaces at the grain boundaries allow the water to be released during the second stage of decomposition. The decomposition of HOA ceramic material to TCP starts on the surface at the points of defects, pores

and grain boundaries. The TCP grains first coated the entire surface of the sintered ceramic material and only then its thickness starts to grow. The time dependence of layer thickness is described by the parabolic law. The diffusion of water toward the surface is the rate-determining step for the thermal decomposition of HOA and TCP. Qualitative phase analysis of HOA decomposition products and kinetic analysis proved that the transformation of HOA to TCP proceeds by a diffusion process. However, the diffusion mechanism of decomposition holds only for the sintered HA ceramics. The kinetic analysis of thermal decomposition of the powdered HA showed that the rate of thermal decomposition of the powdered HA is controlled not only by diffusion of water, but also by formation of nuclei of the newly arising TCP phase [96].

In this work, it has been considered that the mechanism of thermal decomposition of the laser sintered HA samples it is not the diffusion mechanism. In order to the laser sintering happens at lower of second, it is possible by formation of nuclei of the newly arising TCP phase (the similar to powder). Fig. 26.4 shows the laser sintered sample that confirms this assumption.

Fig. 26.4 showing the HA laser sintered sample at P: 18W, BS: 10 mm/s, AED: 430.2 cal/cm².

The laser sintering process is very rapid compared to a classical furnace (around 500 °C/h) in which amorphization of secondary phases can be expected. The laser

sintering process at the order of milliseconds at high temperatures represents a typical thermo-kinetic. The amount of hydroxyl ion removal depends on the heating time and the intensity of the heat source. At the high energy intensity of laser (AED: 717 cal/cm²), the dehydroxylated region forms an amorphous phase. The amorphous phase is illustrated in Fig. 27.4a as the rise above the background. The amount of amorphous phase in this case is found to be approximately 70 wt %. Therefore, a more ACP will form from the melted HA as a result of the high energy density of laser and the rapid cooling rate of the laser sintering process.

Various intrinsic factors could be responsible for the formation of the amorphous phase. The two most important factors, which determine the glass forming abilities of a material, are the viscosity and the increase in viscosity with decreasing temperature [100]. The phase diagram CaO-P₂O₅ exhibits numerous eutectic points, one of which lies very close to the composition of hydroxyapatite. This infers that the cooling of a hydroxyapatite melt produces a "liquidus temperature effect" enabling the liquid to cool to lower temperatures before solidification, and increasing the likelihood of producing an amorphous phase. The glass formation tendency is further accentuated by the composition and complexity of the crystal structure of hydroxyapatite. Phosphate tetrahedra are glass formers and the large entropy of fusion, could accentuate the glassforming ability of hydroxyapatite [101, 102].

The free energy of the hydroxyapatite formation is larger than oxyapatite, and hence, the driving force for nucleation of hydroxyapatite is higher. The hydroxyl-depleted area is thus more sensitive to the cooling rate and remains as an amorphous phase under rapid cooling conditions [103, 104].

Laser sintering produces the amorphous phase, not only due to the high cooling rate but also to the removal of hydroxyl ions, which it make difficult for forming the crystalline phase. The hydroxide content can be controlled either by processing parameters or, alternatively, by the powder-processing stage. Obviously, water molecules play an important role in promoting the transformation of amorphous apatite to HA crystalline in the experiments, here.

The DTA curve of sample (with 70 % glass) shows an exothermic peak at around 880 °C (Fig. 28.4). The exothermic process is related to crystallization of the amorphous phase that can be proved by XRD and FTIR. Therefore, the sample is heated at 880 °C for 3h with the heating rate of 1 and 5° C. The specimen is examined by XRD after the heat treatment.

Fig. 27.4 X-ray diffraction patterns of the laser sintered HA samples at (a) as-laser sintered at P: 30 W, Bs: 10 mm/s, AED: 717 cal/cm² and samples of post heat treatment in air at (b) 3 h at 880 °C (rate of heating of 5 °C/min) and (c) 3 h at 880 °C (rate of heating of 1 °C/min)

Figs 27.4b, c show the amorphous phase transformation to the crystallin phase after the heat treatment. The heat treatment of the laser sintered samples at the temperature of 880°C has led to gradual recrystallization of apatite and tricalcium phosphate. This appearance is a diffusion process in order to the heating rate of 1°C/min was more effective for crystallization. The peaks become sharper and the amorphous hump nearly disappears after the heat treatment. The data in Fig. 27.4 suggest that crystallization is increasing while those indicate that a more transformation of the amorphous to HA requires the heating rate of 1 °C/min. The crystallization requires more time for diffusion of the atoms or groups into lattice sites.

The recrystallization of the amorphous phase during the heat treatment usually consists of nucleation and growth of the nucleus. The nucleation rate and growth velocity (u) of crystal nucleases are in proportion to the diffusion coefficient, which is $D = D_0 \exp(-f/kT)$, where T , f , D_0 , and k represent the absolute temperature, the activation energy for the diffusion, the diffusion constant, and Boltzman's constant ($k = 1.38066 \times 10^{-23}$), respectively [105].

Also, FTIR spectra has shown in Fig. 29.4 reveals that the heat treatment enables the samples to react with the air moisture and to incorporate hydroxyl ions into the amorphous structure. Water molecules can be easily reacted with the amorphous apatite and OH groups fill the lattice vacancies, which are resulted from the dehydration of HA during laser sintering.

Regaining of OH⁻ ions from the atmosphere can be followed via FTIR spectra, as shown in Fig. 29.4. The OH⁻ bands at 630 and 3572 cm⁻¹ and the PO₃⁻⁴ peaks at 961, 1049 and 1092 cm⁻¹ become more prominent after heat treatment at 880 °C and are sharper for the heat treated samples with the heating rate of 1 °C/min than for those given the heating rate of 5 °C/min.

Of course, after laser sintering, the HA is dehydroxylated and transformed into oxyapatite (OHA) and partly decomposed to TCP and C₄P depending on the laser sintering conditions. These crystal types and the amorphous phase of calcium phosphate are more soluble than HA [106]. Therefore, the crystallinity of the HA layers is thought to play an important role in determining the solubility of the HA parts. In this study, a post heat treatment can be employed on the as-received laser-sintered HA in order to improve the crystallinity of the samples.

4.6 Conventional sintering of the HA layers

The layer-wise HA samples with 75 wt% solid were sintered at the temperature range of 1000-1300 °C for 2-3 h.

4.6.1 Microstructure of the sintered HA layers

The typical density values of the sintered products are plotted in Fig. 30.4 versus the sintering temperatures for 2 h soaking time. The increased densification observed as a function of temperature has reached a maximum of 99.1% of theoretical density at 1300°C. Scanning electron micrographs of the polished and etched surfaces of the sintered layers are presented in Figs. 31.4(a)-(d) indicating a uniform grain-size distribution of 1-5 μm . A comparison of Figs. 31.4(a)-(d) reveals that some grain growths occur by sintering at the higher temperature and higher soaking time.

Fig. 32.4 compares the pore size distribution of the conventionally sintered sample at 1300 °C (2h) with the laser sintered sample at P: 24 W, BS: 60 mm/s, AED: 95.6 cal/cm². The laser sintered sample have the broader pore size distribution.

4.6.2 Composition of the sintered HA layers

The HA sample sintered at 1300 °C was pure single phase HA, as shown by the X-ray diffraction presented in Fig. 33.4. The reflections of the XRD spectrum agree very well with the as-received HA powder.

Fig. 33.4 XRD pattern showing of I)HA powder II)conventionally sintered HA layers

4.7. Laser sintering of the HA-glass composite layers

In the present work, glasses containing Na_2O - CaO - P_2O_5 were prepared (see; chapter3). Figs. 34.4 a, b and 35.4 show the morphology and the particle-size distribution of the glass powders after 24 ball milling, respectively.

Fig. 34.4 The morphology of the as- prepared glass powder (a) x 200 magnification (b) x 2000 magnification.

Fig. 35.4 The particle-size distribution of the as-prepared glass powder.

In this study, we have investigated the microstructure and the composition of HA by introducing small quantities of calcium phosphate glass as a sintering additive.

4.7.1 The effect of laser parameters on microstructure

Fig. 36.4 shows interconnected pores with the pore sizes up to $60\text{ }\mu\text{m}$ for the laser sintered samples with 6 and 13 wt% glass. These samples have a high levels of porosity with a wide range of pore sizes. At this condition, it has not been feasible to measure the matrix grain size because of the high porosity present in the composite materials.

Fig. 36.4 Surfaces of the laser sintered samples (P: 20 W, BS: 80 mm/s, SS: 100 μm , AED: 59.75 cal/cm²): (a) 6 wt%, (b) 13 wt%.

As illustrated in Figs. 36.4 to 39.4 by decreasing the beam speed and the scan spacing as a result of increasing the energy density of laser, the pores sizes and content decreases. It seemed that the predominant mode of the glass-reinforced composites is a transgranular process. A steady increase of the grain size of the HA matrix with increasing the glass content, for the all composites, can be seen in Figs. 36.4 to 39.4. By comparison of the HA composites with the HA, can be suggested that the glassy phase increases the mass transport during the laser sintering process with abnormal grain growth. Correspondingly, at the higher energy density of laser, which is

reflected in the higher activation energy values occurs complete densification (Fig. 39.4).

Fig. 37.4 surfaces of the laser sintered samples (P: 20 W, BS: 60 mm/s, SS: 100 μm, AED: 79.67 cal/cm²): (a) 6 wt% glass, (b) 13 wt% glass.

Fig. 38.4 Surfaces of the laser sintered samples (P: 20 W, BS: 80 mm/s, SS: 50 μm, AED: 119.5 cal/cm²): (a) 6 wt% glass, (b) 13wt % glass.

Table. 2.4 shows the density of the HA laser sintered with 6 and 13 wt% glass at different values of energy density of laser. In the present study, the dense and porous

triphasic bioceramics are produced by laser sintering of glass-reinforced hydroxyapatite.

Fig. 39.4 surfaces of the laser sintered samples (P: 24 W, BS: 30 mm/s, SS: 100 μm , AED: 191.2 cal/cm^2 (a) 6 wt% glass, (b) 13 wt% glass.

In Fig. 40.4, the pore size distribution of the HA laser sintered sample has been compared for 6 and 13 wt% glass at case of AED: 59.75 cal/cm^2 . The size of the maximum pore population is gradually shifted towards larger pore diameters for the samples containing 13 wt% glass.

Table. 2.4 The density of the laser sintered HA with 6 and 13 wt% glass.

AED (cal/cm^2)	Density (% theoretical density)	
	6wt% glass	13wt% glass
59.75	72.8 \pm 0.7	76.1 \pm 0.8
79.67	83.2 \pm 0.9	86.8 \pm 0.7
119.5	91.2 \pm 0.9	92.8 \pm 0.9
191.2	96.4 \pm 0.7	98.1 \pm 0.6

Fig. 40.4 Pore size distribution of the laser sintered HA-glass reinforced samples at P: 20 W, BS: 80 mm/s, SS: 100 μm , AED: 59.75 cal/cm^2 with (\blacktriangle) 6 wt% glass, (\bullet) 13 wt% glass.

Finally, the largest pores that appear at medium energy density of laser are due to the simultaneous motion and growth of grains. The motion of grains causes pore expansion, whereas the congregation reduces the total open porosity.

4.7.2 The effect of laser parameters on phase composition

Fig. 41.4 shows the phase composition of the HA laser sintered samples with 6 wt% glass at an energy density of 59.7 cal/cm^2 . It reveals the presence of HA, α -TCP and β -TCP phases after laser sintering.

Fig. 42.4a, b show the phase composition of the HA laser sintered samples with 13 wt% glass at an energy density of 59.7 and 119.5 cal/cm^2 , respectively. As the energy density level of laser increases, the amount of other present chemical compounds also increases. Table. 3.4 shows the quantitative phase analysis results for the laser sintered HA samples with 6 and 13 wt% glass.

Fig. 41.4. XRD patterns of the laser-sintered HA layers with 6 wt % glass at P: 20 W, BS: 80 mm/s, SS: 100 μm , AED: 59.7 cal/cm².

The final microstructure consists of HA, α -TCP, β -TCP and glass. In fact with addition of the higher glass amount, the transformation of HA into α , β -TCP is the more extensive. At high sintering temperatures (>1200 °C), β -TCP is partially transformed into α -TCP.

The use of P₂O₅-glasses as a sintering aid has caused the transformation of HA into β and α -TCP phases. Furthermore, phosphate glasses are known to facilitate the decomposition of the HA phase to β -tricalcium phosphate (β -TCP) and can also lead to further inversion of the β -TCP phase to α -tricalcium phosphate (α -TCP). These phase changes can be brought about by ionic substitutions between the glass and HA that occur during liquid phase sintering in which the extent of substitution can depend on the chemical nature of the glass. The glass causes breakdown of some of the HA to form secondary phases. This was proposed as a mechanism for reinforcement of the composite. Some glasses may contain mineral ions such as Na⁺ or Mg²⁺ which could be responsible for structural changes in the HA lattice during the sintering process. Physical considerations must be highlighted to explain the effect of these phosphate glasses on HA. The phosphate glasses, when incorporated into HA, melt at lower

temperatures compared with HA and can act to increase densification by enhancing the sintering mechanisms. Although, this process is known to improve the material mechanically, it has been of importance in this study to emphasize on how this may be correlated to the changes in density, porosity and in particular, shrinkage [107].

Fig. 42.4. XRD patterns of the laser sintered HA layers with 13 wt % glass at (a) P: 20 W, BS: 80 mm/s, SS: 100 μ m, AED: 59.7 cal/cm²; (b) P: 20 W, BS: 80 mm/s, SS: 50 μ m, AED: 119.5 cal/cm².

Table. 3.4 Quantitative phase analysis results of the laser sintered glass-reinforced HA samples.

Composition of sample (wt% glass)	Laser sintering conditions				Phase composition (%) ± 2		
	P(W)	BS(mm/s)	SS(μm)	AED(Cal/cm^2)	HA	α -TCP	β -TCP
6	20	80	100	59.7	87	4	3
	20	80	50	119.5	77	12	5
13	20	80	100	59.7	75	7	5
	20	80	50	119.5	46	27	14

Georgiou et al [107] has shown that approximately at 900 °C HA starts to undergo shrinkage but, compositions of both 2.5 and 5 wt% glass undergo shrinkage at approximately 1000 °C. Shrinkage is governed by the rate of densification and through reduction in porosity. It is therefore important to mention any correlation between porosity and shrinkage and also if additional factors such as secondary phases correlate with changes observed for shrinkage.

Both the glass-HA materials contain a fraction of β -TCP and α -TCP secondary phases sintered at 1200 and 1300 °C. Decomposition of HA to β -TCP and subsequent inversion to α -TCP introduces an increase in unit cell volume, which may explain why the glass-HA materials undergo less shrinkage. A higher percentage of glass leads to less shrinkage.

This also applies to the differences in the level of shrinkage between the glass-HA materials with 6 and 13 wt% glass, since the glass-HA (13 wt%) contains a higher amount of the β and α -TCP phase (that β and α -TCP have the larger unit cell volume than HA). These differences seen in porosity level show some correlation with the level of shrinkage. However, it seems that the presence of the secondary phases predominate the level of shrinkage.

Figs. 43.4 a, b show the laser sintered glass-reinforced layers with 50 layers deposited on the ceramic substrate and 3-dimensional parts, respectively. Visual inspection of the sintered parts revealed no bubbling, delamination or cracking.

(a)

(b)

4.8 Conventional sintering of the HA-glass layers

4.8.1 Microstructure of the sintered HA-glass layers

Figs. 44.4, 45.4 show microstructure of the conventionally sintered samples with 6 and 13 wt% glass. Glass-reinforced HA composites show larger grain size than the HA sintered at all sintering temperatures.

Lower activation energies for grain growth are observed for the composites compared to the unreinforced hydroxyapatite, which should be attributed to the presence of a liquid glassy phase that promotes atomic diffusion during the sintering process [107, 108].

Fig. 44.4 SEM images of the polished and etched surface of the conventionally sintered HA composite at 1200 °C for 2 h with (a) 6 wt% glass, (b) 13 wt% glass.

Fig. 45.4 SEM images of the polished and etched surface of the conventionally sintered HA composite at 1300 °C for 2 h with (a) 6 wt% glass, (b) 13 wt% glass.

Steady increase of grain size is observed when the sintering temperature increases, for all composites. However, in some cases, the grain boundaries could not be clearly observed. The density data of the HA samples with 6 and 13 wt% glass are given in Table 4.4. It can be observed that the bulk density increases with increasing amounts of glass content. The full densification over 99.5 % of the theoretical density is

achieved for 13 wt% glass samples at 1300 °C. Therefore, the samples with 13 wt% glass contain enough glass to completely coat the HA during sintering, but not so much glass that the properties of the composite are governed by the glass. In Fig. 46.4, the pore size distribution of the conventionally sintered HA sample is compared with the laser sintered layers of HA sample with 13 wt% glass. The laser sintered sample have the boarder pore size distribution than the conventionally sintered sample.

Table. 4.4 The density of 6 and 13 wt % glass as function of temperature

Sintering temp. (°C)	Density (% theoretical density)	
	6wt%	13wt%
1200	97.2 ± 0.6	98.1 ± 0.5
1300	99.1 ± 0.5	99.5 ± 0.6

Fig. 46.4 The pore size distribution of the HA-glass reinforced samples with 13 wt% glass (▲) laser sintered (●) conventionally sintered.

4.8.2 Composition of the sintered HA-glass layers

During the conventional sintering, the CaO-P₂O₅ glass reacts with HA and so some α , β -TCP are formed in the microstructure as demonstrated by X-ray diffraction analysis.

Fig. 47.4 XRD pattern of the HA conventionally sintered a 1300 °C with 6 wt% glass.

Fig. 48.4 XRD pattern of the HA conventionally sintered a 1300 °C with 13wt%glass. Figs. 47.4, 48.4 show the phase composition of the HA conventionally sintered at 1300 °C with 6 and 13 wt% glass, respectively.

It reveals the presence of HAP, α -TCP and β -TCP phases after conventional sintering. The amount of TCP depends upon the content of the glass added to prepare

the composite. In fact with addition of the higher glass amount, the transformation of HA into α, β -TCP is the more extensive. At high sintering temperatures (>1200 °C), β -TCP is partially transformed into α -TCP.

A possible explanation for the lower sintering temperature required for having triphasic bioceramics when using glass powders rely on the sintering mechanism. The glass used in these studies has a low liquidous temperature and sintering occurs with the presence of liquid phase, which causes a better interaction between particles and thus favors the phase transformation. This is accounted for by the promoting the effect of the liquid phase formed in firing on the rearrangement of the crystal lattice of hydroxyapatite and its transformation into tricalcium phosphate. Tricalcium phosphate identified starting at 1150 °C reflects the part of hydroxyapatite that has recrystallized with participation of the liquid phase. This is related to decomposition caused by the addition of the glass, which is highly reactive at high temperatures and forces major chemical changes associated with the hydroxyl site. Furthermore, ions from the glass may take a more interstitial role, modifying the unit cell and not allowing the expected changes that normally occur on sintering HA to take place [107, 108].

5. Conclusion and outlook

The present study is aimed at investigating the optimization of an aqueous dispersion of HA powder synthesized by powder pre-treatments. The project has been involved in several areas of effort, including formulation of a low-shrinkage slurry system, development and production of HA layers suitable for the laser sintering process. Also, this work includes the direct laser sintering process without using a binder in the slurry and compares it with conventional sintering of layers. All of these interrelated parameters must be controlled so that sintering defects are prevented.

The rheological properties of the hydroxyapatite slurries has played an important role in facilitating the layering operation. The dispersing and stability behaviour of HA powders in aqueous media was monitored by the particle size, viscosity and zeta potential analyses as a function of pH of the slurry and the quantity of two dispersing inorganic and organic agents. Process feasibility and quality is dependent on the processing parameters like the solids loading, slurry rheology, deposition rate and drying rate. Each of these can affect the properties of ceramic layers such as thickness, surface quality, microstructure and porosity. The current work was focused on the preparation of well-dispersed HA ceramic slurries for layer-wise deposition. The influence of the powder calcination temperature on phase composition, specific surface area, optimum concentration of dispersant and rheological behaviour was studied. The calcination temperature affects on the surface area that plays an important role in the rheological behaviour of the suspensions. The specific surface area of the starting powder strongly influences the maximum solid loading of the suspensions, which show complex rheological behaviour.

The most influential process parameters on microstructure and composition of the samples are found to be the laser power, the laser beam speed and the scan spacing. The penetration depth of the laser is increased by increasing the laser power and decreasing the beam speed. In the LSD process, the largest slice thickness is limited by the penetration depth. When the beam speed and the laser power vary in the range of 10 - 60 mm/s and 18 - 24 W respectively, the maximum slice thickness achieved is 100 μm . The sintered samples has a pore size of 40 - 80 μm . After laser sintering, the presence of α -tricalcium phosphate (TCP), tetracalcium phosphate (C_4P) and amorphous calcium phosphate (ACP) are detected. The presence of these phases depends on the laser sintering conditions. The X-ray diffraction, FTIR and SEM have

been used to investigate the influence of the laser parameters on the formation of the phases of TCP and ACP that are beneficial for accelerated fixation and remodeling of the prosthesis.

The laser sintered samples have a high porosity that the pore size of the samples could be expressed as a function of the laser parameters and the green density of layer.

Also, this present research includes comparing of the direct laser sintering process with the conventional sintering of layers.

This study shows tricalcium phosphate coexisting with hydroxyapatite, an amorphous phase and perhaps oxyapatite at low energy levels of laser. The presence of tetracalcium phosphate at higher energy levels has been proved. The crystallinity and purity of HA decreased with increasing laser power and decreasing scan speed.

It is desirable to increase the crystallinity of the HA laser sintered parts and decrease the fast-degraded calcium phosphates. There are two ways to increase the crystallinity of the HA parts: varying of the laser sintering parameters and post-heat treatment. To achieve an optimum resorbability of the material, studies can be focused on the multiphasic calcium phosphate ceramics composed of HA and TCP and amorphous.

The results indicate that phase transformations are produced by (a) preferential removal of hydroxyl and phosphate leading to a change in melt compositions, and (b) the high cooling rate due to the laser sintering process. Hydroxyl group removal promotes the amorphous phase and oxyapatite.

Hydroxyapatite has two intrinsic properties that enable it to form an amorphous phase. First, it is made up phosphates, which are glass formers, and second, the composition of hydroxyapatite is very close to the eutectic composition, thus inducing a liquidus effect. The high energy interaction of the laser with the powder layer associated with the rapid heat transfer may be sufficient to form the amorphous phase. The rapid solidification arising from the high cooling rates in laser sintering has produced amorphous phases from crystalline hydroxyapatite. The laser sintering produces the amorphous phase, not only due to the high cooling rate but also to the removal of hydroxyl ions, which make it more difficult for the crystalline phase to form. The hydroxide content can be controlled by the processing parameters or, alternatively, by the powder-processing stage. Calcination at higher temperatures reduces the hydroxyl content, which affects on further dehydroxylation during laser sintering. Thus, a hydroxyl deficient feedstock material will more likely give rise to an amorphous phase compared to a powder with high hydroxyl content.

Formation of the amorphous phase can be attributed to many factors and can be discussed from the kinetics and thermodynamics perspectives. The free energy of formation is larger for

hydroxyapatite than oxyapatite (a completely dehydroxylated hydroxyapatite) and hence, the driving force for nucleation of hydroxyapatite is higher. The hydroxyl-depleted area is thus more sensitive to the cooling rate and remains as an amorphous phase under rapid cooling conditions.

Despite these intrinsic factors and properties of the feedstock material, the laser sintering conditions play a role in forming the amorphous phase of hydroxyapatite layers. The laser parameters such as laser power, laser beam speed and scan spacing contribute the amount of amorphous phase formed. The first parameter that is recognized to produce the larger level of amorphicity is the beam speed. The longer time at the elevated temperature produces more dehydroxylation, which influences the formation of the amorphous phase.

Laser sintering, a newly investigated technique for producing the HA bulks, has the ability to produce both the dense and porous and both the crystalline and the amorphous bulks.

Also, in this study, the fabrication of the porous and dense glass-reinforced HA composite by laser sintering and conventional sintering has been investigated. In the study, a phosphate glass is successfully developed that can form a melting glass within milliseconds when exposed to a continuous-wave CO₂ laser of medium energy density in the glass-reinforced HA composites. The CaO-P₂O₅ glasses with the addition of Na₂O are used as a sintering aid of hydroxyapatite, and thus glass-reinforced hydroxyapatite composites are obtained.

Using a laser sintering process, we successfully fabricated a porous body with a continuous pore structure of 30-60 μm diameter. The glasses have promoted significant changes in the microstructure of the composites, namely by the formation of tricalcium phosphate secondary phases, β and α -TCP. The final microstructure consists of a triphasic bioceramic after the laser sintering.

The addition level of 13 wt% glass has caused a higher transformation of HA into the secondary β - and α -TCP phases than the 6 wt % glass ones. By increasing the energy density of laser, the porosity of the composites has decreased faster than the sintered HA and all composite samples showed a higher densification than HA. The densification has occurred by liquid formation and spreading, improving the diffusion mechanism. A strong bonding is developed between the HA and the phosphate-based glasses, which acts on the solid HA particles reducing the interfacial energy and eliminating porosity.

Finally, the largest pores that appear at the medium energy density of laser are due to the simultaneous motion and growth of grains. The motions of grains cause the pore expansion, whereas the total open porosity is reduced by congregation.

In this work both the dense and highly porous structures HA and glass-reinforced hydroxyapatite were obtained. The multi-layers up to 50 layers have also been obtained for the HA/glass system.

This report was focused on the phase compositional and microstructural changes observed by means of XRD, FTIR and SEM after laser sintering and the conventional sintering.

The relationship between the composition and microstructure of the porous HA and HA-glass composite with its bioresorption needs to be investigated in detail in further research. An appropriate porosity can be coupled with bioactivity of bodies provides a growth of the bone tissue to achieve a full integration with the living bones, that this subject is recommended for future work.

Also, it is suggested to revolve around laser-sintered second phase-reinforced HA (such as HA/zirconia) composite in order to evaluate the mechanical properties. Many studies have promoted ceramic/ceramic bio-composites as a potential for implant applications. One possibility is the reinforcement of HA with particulate zirconia. Previous researches have shown that the addition of ZrO_2 as a second phase to HA significantly increases the bonding strength of composite material. Consequently, the addition of ZrO_2 can improve the mechanical properties of the LSD parts.

In LSD system, spot size varies as a function of axial position. The spot size is generally increased as a function of distance from the beam waist. Therefore, effect of this parameter on the laser sintered parts can be investigated in future work.

Lebenslauf

Zahra Sadeghian

26. 08. 1970

geboren in Tehran/Iran als Tochter von Hasan
und seiner Ehefrau Kokab, geb. Esfahan
Staatsangehörigkeit: Iranisch

1976 - 1981

Grundschule in Tehran/Iran

1981 - 1987

Rezvan- Gymnasium in Tehran/Iran

Schulabschluss mit Abitur am 20.06.1987

1987 - 1994

Studium der Werkstofftechnik an Technischen
der Universität Science and Technology of
Abschluss des Studiums mit dem Master
Science of Materials Engineering am 1.11.1994

1994 - 1998

Wissenschaftliche Mitarbeiterin am Institut für
Material Engineering der International
University of Qazvin

1998 - 2002

Angestellte am Saipa Malleable Auto Co.

01.01. 2003 - 31.03.2005

Wissenschaftliche Mitarbeiterin am Institut für
Nichtmetallische Werkstoffe der TU Clausthal
